## ORIGINAL ARTICLES.

### THE STRUGGLE OF THE BODY AGAINST TUBERCULOSIS AND ITS IMMUNIZATION.*

BY PROF. EDOARDO MARAGLIANO,
OF GENOA, ITALY.

I.

I WISH at first to express my hearty thanks to the committee of organization of the Congress, which, in asking me to hold the conference at the general assembly, has done me the honor to permit me to represent my country in its scientific aspect.

I would like to speak to you upon subjects relative to tuberculosis, and I have chosen that one to which for more than thirty years I have devoted, both in the laboratory and the clinic, the best efforts of my mind.

The existence of an antitoxin for tuberculosis and the possibility of its application to the cure of tuberculosis, was announced for the first time by me in Bordeaux, in 1895. The truth which I announced was the object of many discussions; it is, however, thanks to the successive labors of many savants, a definite addition to science. Many workers in laboratories, among others, Behring and Arloing, have verified the possibility of obtaining a true tuberculous antitoxin from animals, and a host of physicians have recognized its practical application in the treatment of human tuberculosis, and its efficacy when the disease is in a stage that is not too far advanced.

To-day I wish to call your attention to a problem of a higher order even than that of the cure of tuberculosis, and to speak to you of the natural means that the body possesses and employs to combat this disease, and of the means by which one can create in it an artificial immunity against tuberculosis.

This is the problem which for some years has held my attention and on which I propose to speak, pointing out in this thesis the results that have thus far been obtained.

I must, in the first place, tell you that these results are the fruit of the labors, not only of one person, but of a school. They are, in fact, the experimental and clinical researches publicly carried on, either in my Medical Clinic or in the Institute for the Study of Infectious Diseases which I founded and where a band of eager workers find at their disposal all necessary material for their research work, observation, and experiments.

There is a fact that always gives food for reflection to those who are interested in tuberculosis; viz., in spite of the enormous diffusion of the tubercle bacillus in the midst of cities, a great many persons remain unaffected by the terrible disease.

Experimental pathology, it is true, has demonstrated that no absolute immunity exists, if very large quantities of a virulent culture be introduced into the body. But to carry this proposition into actual practice is not permissible. Is it not just, on the other hand, to state that never does one verify in spontaneous infections what happens in those that are experimentally induced, where one injects into the veins large quantities of the tubercle bacillus?

For the number of pathogenic micro-organisms introduced at one time, and the avenues of entrance are two factors by no means to be neglected in the induction of an infectious process. The blood offers, as is well known, the most favorable means for a rapid diffusion of the bacillus.

This is the reason why, in spite of the possibility of artificially infecting any organism whatsoever, it is proved by experience that it is no less true, that a great many persons exposed to the tubercle bacillus remain free from infection, and that we physicians ought to recognize clinically and practically, the existence of a certain class of persons possessing a natural immunity towards tuberculosis, such as we would like to establish in the human body.

In view of the facts we must ask ourselves why this immunity is possessed by some, and does not exist for others, and by what circumstances it can be strengthened or made to disappear. It is to the study of this problem that my coworkers and I have directed our attention.

I will first tell you what was our point of departure. We ought, in the study of the pathology of the products of disease caused by tuberculous infection—as in that of the greater number of infectious diseases—consider on the one hand the tuberculous poisons created by the changes in the tissues and the plasma of the body, and on the other the bacillus that produces these poisons.

Tuberculous poisons have a double origin, a part are the secretions of the bacillus during its period of biological activity; the others are enclosed in the protoplasm of their own bodies. These latter are of special importance, as the dead bacilli can create in the tissues similar changes to those created by the active and living bacilli; and it is just by means of these latter poisons that the dead bacilli exercise such power.

Their poison, as I have been able to demonstrate by a series of researches already well known, and of which I gave a full account to the French Congress on Tuberculosis, in Paris, in 1898, can be completely withdrawn from the

* Read at the International Medical Congress, held in Madrid, April 23 to 30, 1903. Contributed to MEDICAL NEWS, La Presse Médicale and Deutsche medicinische Wochenschrift.

bodies of the bacilli, by a prolonged boiling in water. They show a pathogenic and necrotic power over the tissues with which they come in contact.

Among our researches, I will mention particularly those of one of my associates, Dr. Badano, who has demonstrated that the poisons of the bodies of the bacilli injected into the trachea cause the development of areas of bronchopneumonia in the lungs of animals.

To be able to defend itself victoriously against the attacks of the tubercle bacillus, it is necessary that the body should, at the same time, neutralize the tuberculous poisons, prevent the multiplication of the bacilli, and destroy those that have already found their way into the organism.

I place, as of first importance, the neutralizations of the tuberculous poisons, expecting that if this condition is not met, these poisons, by altering the character of the tissues, will create a soil still more favorable for the development of the bacillus.

We have proved this by a very simple experiment. When one injects into the thigh of a guinea-pig a small quantity of tuberculous poisons, $^1/_{10}$ c.cm., and if one inoculates the animal at the same time with a small dose of an active and virulent culture, the bacillus infection proceeds much more rapidly in the infected animal than in the controls.

Does an organism in a good physiological condition possess a means of defense against tuberculosis?

In order to answer this question, we have resource to a series of researches intended to show whether the sera of different animals do or do not contain antitoxic materials that neutralize the tuberculous poisons. These fundamental researches were only made possible by my work upon tuberculous poisons.

In short, I found myself balked at the beginning of my studies with an inactive principle with which it would have been impossible to kill the healthy guinea-pig, by means of these poisons. I used at that time a product that was inconstant in its nature, vacillating in its toxic quality, and imperfectly specific; varying because the richness in toxic material is variable from one culture to another, imperfectly specific because the 50 per cent. glycerin contained in the tuberculin modified its specific character, the glycerin being in itself a toxic product. But we succeeded by our studies in providing ourselves with a product whose dose was constant, having 100 toxic units to the cubic centimeter; that is to say, in a cubic centimeter a subcutaneous injection would surely kill a guinea-pig weighing 100 grams.

Having thus reduced the power of killing to an exact art, for we possessed a sure specific poison, and an exact method of dosage, it now remained to see whether the serum of man and of animals would have any neutralizing power when used in the guinea-pig; and if so to calculate exactly the antitoxic value of the different sera.

These experiments have shown us that the serum of robust and healthy men, contains positively defensive elements, for a dose of tuberculous poison that would be surely fatal in a guinea-pig is no longer so, when it is first mixed with a certain quantity of human serum. In repeating the experiments with the serums of different healthy animals, we have found that some do, and others do not, possess this antitoxic property; we find that human serum stands the highest in the scale of antitoxic power. That of the cow, calf, dog, cat, stag, horse, and above all of the turkey and the pig also contain antitoxic elements in different proportions. There is, however, no trace of them in the sera of the guinea-pig and rabbit.

Relative to the bacilli we have found that the same sera of healthy subjects if added in different proportions to the cultures were capable of influencing their development, and we have really found that several of them exercised a very decided influence, and have prevented the development of the bacilli.

The most powerful sera are those of the man, of the pig and the calf, then come those of the cow, the horse, the dog, the ass, the stag, and the rabbit, while the power of that of the guinea-pig is reduced to zero. The bacillus of tuberculosis may be even cultivated with ease in the pure serum of the guinea-pig.

The sera of the animals just mentioned, are endowed with still another property, that of agglutinating homogeneous cultures of the tubercle bacillus, according to the methods of Arloing and Courmont, which is the surest. This fact, affirmed by Arloing and Courmont, has been clearly confirmed by my own researches. The sera of the horse, the ass, the stag, the sheep, the dog, and the rabbit all possess a certain power, more or less marked, of agglutination. That of the guinea-pig, on the contrary, does not as a rule, possess it at all.

Agglutination, it is useless to call it in question, is the expression of a process of immunization, of a special defensive energy of the organism, as I have understood from the publication of the works of Widal on agglutination in typhoid fevers, a phenomenon which the author interprets as a reaction to infection.

Tuberculosis does not escape this law, which is to-day universally admitted. Koch himself expressed the opinion that agglutination in tuberculosis would be the exponent of the immunizing reaction. This phenomenon is, in fact, related to the presence in the circulation of substances that exercise a particular action on the bacillus of tuberculosis.

The agglutinating power is thus a new proof of the existence of defensive materials in animals. The serum of a healthy man, showing no actual sign of tuberculosis also possesses a certain power of agglutination. This last proposition, affirmed first by Arloing has been confirmed by our own experiments, in our Institute, and by those of Romberg, at Marburg.

But in addition to these energies that the animal organization usually possesses to defend itself against tuberculosis, there exist others whose existence is induced by the presence of the bacilli and their poisons. These are represented —as I can affirm after a long series of experiments undertaken for several years, on different animals, and published in 1895, and continued to this day—by the extraordinary production of antitoxins, by bacteriolysins and agglutinins.

If one determines, according to my method, the antitoxic power of the blood of an animal, as opposed to tuberculous poisons, and then inoculates it methodically with small quantities of these poisons, one sees, at the end of a certain time, that the antitoxic power of its serum increases considerably. We have verified this fact in the dog, the ass, the horse, the stag, the sheep, the cow, and last, in man. This increment of antitoxic power, which may be perceived at the end of a month, becomes considerably greater, so much so, that in several horses that started with only 100 to 200 antitoxic units to the centimeter, the increase amount progressively to 1,000, 2,000, 4,000, and 8,000. I have established the fact that in a healthy man, at the end of a month of regular inoculations, the antitoxic units can be raised to double or triple the amount of those at the beginning of the treatment. This ability of the human organism to produce, as a defensive reaction against tuberculous poisons, defensive antitoxic elements, is a fact that is to-day universally admitted. Perhaps it has not been forgotten that I was the first to demonstrate it, at a time when the possibility of obtaining a tuberculous antitoxin was not even suspected.

What I stated for the first time in the month of August, 1895, in Bordeaux and London, was confirmed by numerous observers, among whom was Behring, who repeated it in several communications, notably in that to the Congress of Hygiene in Madrid, 1898.

And if some few observers failed to obtain the same results, it was the fault of technical errors arising largely from the use of glycerinized tuberculin. It happened in some instances that the experimenters injected into their guinea-pig along with the tuberculous poisons, toxic quantities of glycerin, which destroyed the value of their results.

The introduction of the bacteria into the organism stimulates in the same way the development of these new bactericidal energies. It was evident when an animal was injected with my aqueous tuberculin—which was nothing more than aqueous extract of the bodies of the bacilli —that this development was really an inoculation of dried or living bacilli. The latter particularly when they are prepared in a convenient form, start up in the inoculated animals, a formation of substances that are strongly bactericidal.

This may be proved in different ways. The blood of different animals is collected, and is tested to see whether the living virulent bacilli lose their vitality from contact with serum that is suitably prepared. The object of the research in such cases, is to see, whether, and in what proportions, the sera added to the culture modify the development, whether the bacilli once brought in contact with the sera, can thereafter develop regularly. In short, whether the bacilli, after coming in contact with the sera for a greater or lesser time show any of those necrobiotic changes that are characteristic of their death and destruction as studied in my Institute. By all these experiments we have been able to prove that the sera of all animals treated with different tuberculous materials, possess to a greater or less degree, a baneful action upon the bacilli of tuberculosis.

The first series of experiments show clearly that the bactericidal action is due to substances developed in the animal that furnished the serum that contained them in solution. It deals with a destruction of the bacilli, that has nothing in common with other organic energies, such as those presented by the phagocytes, and other tissue elements.

This does not, however, prevent me from admitting the rôle that the leucocytes and the organic elements may play in the formation of these substances, also the destruction that the leucocytes and these cellular elements exercise on the tubercle bacilli; but I maintain simply the undeniable fact that in the serum of inoculated animals there is found, as I have said, certain substances in solution that are capable of nullifying the vitality of the bacilli, and causing their destruction.

In connection with the second series of experiments we studied the power that the serum had of depriving the tubercle bacilli of their infectious properties. In order to demonstrate this fact we inoculated guinea-pigs with virulent bacilli that had been kept in contact with the serum for a varying length of time and after preparing controls waited for the development of the infection. We succeeded by these methods in preventing the development of tuberculosis in guinea-pigs, after an injection of very virulent bacilli, which caused certain infection in the controls.

But I would like to describe still another more striking experiment. We inoculated the peritoneum of a guinea-pig with a certain amount of virulent and active culture, mixed with the suitably prepared serum of a horse. After which, at the end of twenty-four to thirty-six hours, we opened the peritoneal cavity and collected a certain amount of the liquid containing the inoculated bacilli, and used them for the new peritoneal inoculations and to sow the culture tubes. These remained sterile; and as to the inoculated animals they did not take the disease.

The experiences of the controls, however, those that were inoculated but without the addition of the serum, gave positive results.

The dried bodies of the bacilli, and particularly the living bacilli, constitute the material that is the most likely to create in the organism a large quantity of specific bactericidal substance. Viru-

lent cultures of tubercle bacilli injected into the veins of rabbits, along with the serum, remained inert, but there was found a formation both of bactericidal substance and agglutinating materials. Horses, asses, cows, sheep, stags, dogs, rabbits, treated as we have described, have attained a power of agglutinization in the proportion of 1 to 400: as for example, in a cow inoculated with the dead bodies of bacilli. This very significant increase in the power of agglutination proves with certainty the development, in great quantity, of protective bodies in the organism of animals treated by means of dried bacilli, or those that are living and active.

By comparing the agglutinating power of the serum in animals inoculated with tuberculous poisons, with that of animals treated with the bodies of the bacilli, we have found that the agglutinizing power is much stronger in the second case, while the antitoxic power shows itself much more intensely in the animals submitted to injections of poisons.

These experiments tend to show that in the animal organism tuberculous poisons incite the formation of antitoxins, and that it is the bacilli that give rise to the development of these antibodies, making up a highly defensive sum of energies.

We also undertook a series of researches to study the fate of the active living bacteria when they were inoculated under the skin of animals. By a very simple technic, we periodically probed the place of inoculation, and took away small quantities of subcutaneous material, and we were thus able to follow, with the microscope the morphological modifications of the inoculated bacilli, whose fate it is to be little by little swallowed up by the leucocytes, and to undergo, during a greater or less length of time, various phases of necrobiosis, and at last to disappear completely.

Of all the animals on which we have made the experiments, dogs, asses, rabbits, guinea-pigs and rats, the dog seems to be the one in which the destruction of the inoculated bacilli takes place most rapidly; at the end of five days these latter were to a large extent swallowed by the leucocytes, and in a state of complete bacteriolysis, while in the guinea-pig at the end of the same length of time, not only were the bacilli not yet devoured, but they presented almost the same characteristics as they had done in the culture.

At the same time, bacilli injected in small quantities directly into the lung of a healthy rabbit are doomed to destruction. It is thus proved in the most positive manner by our experimental researches, that there are defensive remedies against tuberculosis: one is represented by the natural energies of the healthy body, which is able to defend itself efficaciously against the bacillus of tuberculosis and its poisons; the other comprises the new energies which we see rushing forth when the bacilli or their poisons penetrate the organism.

Would these defensive energies which are found physiologically in the body be the effect of reactions produced by latent tuberculous infections of the past that have been ignored? Or might they rather be congenital energies? Or still, might they not be the result of a unique genetic mechanism?

But let us set aside, for the time being, such questions which would lead us into many discussions, and content ourselves at present with knowing that the organism can have no hope of victory in the struggle against tuberculosis, outside of these two classes of defensive energy. So long as these preserve their integrity, the bacilli are destroyed as soo as they enter the organism, and their poisons neutralized, without there being any tangible sign to warn us of the struggle that is going on in its various phases of development, in a certain local circumscribed portion of the body. I have seen a guinea-pig, the animal that is poorest in defensive energies, resist the hypodermic inoculation of small doses of virulent bacilli, and continue to keep well, and even to increase in weight.

But let us suppose that the defensive energies, those that are normal above all, are not quite complete, there is then established a local focus of tuberculosis, and then there develops by an effect of reaction toward this focus, and toward the bacilli that were multiplying and the poisons that they elaborated, reactive energies, and specific means of defense. The bacilli are destroyed, their poisons are neutralized and a spontaneous cure takes place without any other special intervention, and proclaims the victory of the organism over tuberculous infection.

The defensive powers which depend primarily upon conditions of organic soil, tend to disappear when a change in the condition of the soil arises.

I have been able to convince myself, by a series of experiments on individuals weakened by preceding illness, and on subjects whose nutrition was interfered with, either by excessive fatigue, or by insufficient food, that their serum did not possess enough of the materials of organic defense, that is to say that the neutralizing action toward the tuberculous poisons and the inhibiting action toward the bacilli were not up to the standard.

Therefore I have also stated that the defensive resources of the organism of individuals cured spontaneously of tuberculosis, exactly measured according to my method, increases proportionately according to the degree by which they approach complete cure; and that the presence and the proportion of defensive elements in the body keep pace with the variations of the malady as it progresses towards or away from cure.

These experimental researches only go to confirm what the clinical observations have brought into prominence concerning the particular fatality with which tuberculosis attacks women who are pregnant, or in puerperal condition, or who are nursing. These conditions of organic soil differ in various degrees with each subject.

In reckoning the numbers of bacilli contained

in the inoculating fluid we have inoculated 100 guinea-pigs, and 100 rabbits with exactly determined quantities of the tubercle bacilli. We have been able to determine that 10 bacilli could by themselves produce a generalized tuberculosis in certain subjects, while in others the injection of 500 bacilli remained without effect. These differences in results are not possible, unless one takes into account the slight number of bacteria employed, seeing that 500 is but a trifle in the world of infinitely small things. I note this circumstance because, as I have said, there are no organisms that could withstand the direct inoculation of a very strong dose of tubercle bacilli.

The defensive power, moreover, is not even the same in all the other tissues, as I have been convinced by a very interesting series of experiments. When one injects into the veins of a dog, a gram of virulent tubercle bacilli these become localized in the lungs, and create tuberculous foci, which are forthwith spontaneously cured, and in which at the end of a month one can find no trace of the bacilli. On the other hand, in injecting the same quantity of bacilli into the peritoneum, one finds at the end of a month a well-developed tuberculous peritonitis, and we can easily distinguish between the bacilli in the veins and those in the peritoneum, those in the peritoneum growing and thriving, while the others succumb to their fate in the lung. These conditions of organic soil ought to be considered to a great extent, as acquired, and we ought to consider them in connection with the hygienic conditions in the midst of which the organisms live. The condition of nutrition ought to have first importance and our researches explain the reason perfectly.

Among the conditions of nutrition which create and augment the defensive powers, I will cite the use of alcohol. But, take care, I warn you, I speak of the moderate use of this substance, and not of its abuse which creates on the contrary a diminution of resistance in the body. For I have observed that the very healthy subjects which show the richest defensive material in the blood, without having the clinical signs of chronic alcoholism, have, however, been accustomed rather largely to alcoholic drinks.

From the combined results of our experimental researches, we have been able to get an exact idea of the manner in which the animal organism struggles, or can struggle against tuberculosis, and the weapons with which nature has furnished it to triumph over it enemies. We ought, therefore, to recognize the fact that the best means of fighting against the propagation of tuberculosis is to increase as much as possible the natural defensive forces of the body. Toward this end we have directed all our efforts, all our work and our whole energy. But, gentlemen, we must state that it is not the sanitarium alone that will succeed in diminishing the number of victims of tuberculosis, and protect humanity from its scourge. The sanitarium will not stamp this evil off the earth.

True, I do not doubt that sanitaria constitute a very highly humane source of help to the tuberculous poor, and lend their aid to cure when that is possible, but sanitaria can play no decisive and important rôle in the social prophylaxis of the disease, and they seem to me, looked at from this point of view, more like sanitary cordons and quarantine stations, rather than means of preventing the spread of epidemics.

To create good hygienic environment in the country, and to suppress at the same time all soil suitable to the growth of these germs of disease, according to experience and to science this is the most efficient way to stem the tide of infection. When in a future that is more or less near, our efforts will have succeeded in strengthening the organic soil, and in furnishing it with specific energies that will serve to immunize it against infection, tuberculosis will be vanquished.

II.

Can we hope to see the dawn of this day. I have turned my attention and my studies especially toward this point and will tell you what work has been accomplished if you will have the kindness to follow me a little longer.

The first problem to solve was naturally the immunization of an animal against tuberculous infection, so that autoimmunization in him might be accomplished. This difficulty has been overcome in part. In 1895, in my reference at the Congress of Internal Medicine at Bordeaux, on the serum therapy of tuberculosis, I distinctly announced on the twelfth of August that the animals that furnished me the antituberculous serum, were immune. I did not insist on this, although I expressed myself very explicitly. For chronological reasons, however, it will be as well to revert to it. I declared in this connection that I had rendered immune dogs, asses and horses, and apropos of dogs, I said exactly the following words, which may be found on page 1080 of the official report of the Congress at Bordeaux. *"Progressive vaccinations, according to the methods that I have followed, immunize dogs against the injection of very virile human tuberculosis in their veins."*

These words were spoken by me, as I now recall it, on August 12, 1895. I have continued my experiments in this line, and to-day I can tell you that my animals are still immune. In my Institute are cows, asses, sheep and dogs that are completely immune, some for as long as five years; and I have even succeeded in immunizing rabbits.

I have rabbits which we have inoculated with no effect, with active virulent cultures of human tuberculosis, that killed the controls in from twenty to thirty days.

The possibility of immunizing animals, announced first by me in 1895, was announced anew toward the end of 1902, and in the month of March, 1903, by Behring at Vienna. I was delighed that so eminent an observer had confirmed in the calf what I had affirmed eight years previous, viz., the possibility of vaccinating and im-

munizing animals against tuberculosis, but I hold, as is very natural, that the fact should be recognized that I attained the same results several years before he did.

The vaccination and this immunization may be obtained in different ways and with materials of different kinds. We have succeeded in using materials taken from very active cultures, from dead and dried bacilli, from living and very virulent bacilli, and from an extract of active living bacilli. This extract manufactured by a cold method, without the use of heat or chemical substances is the one by which we have been able to obtain the largest amount of immunizing energy, without running any risk of creating tuberculous infection in the inoculated animal. By means of this process immunization takes place very quickly, and to use it, it is only necessary to resort to intravenous injections.

But setting aside for the time being the method of using it, it is sufficient to say that one can immunize an animal against tuberculosis, and render it impervious to the disease, even so that one can permit a larger quantity of bacilli than one would think possible to enter the tissues and to circulate in the human blood, following the usual conditions in which infection is produced.

In view of these facts it is natural to ask a question that implies another hope. Is it possible to cause by any feasible method such immunization in man?

I have studied the problem from two different points of view, and I have approached from two different avenues. There is the point of view of passive immunization, and that of active immunization.

One may, as is known, bring about passive immunization against infection in an animal, by introducing into its body defensive materials produced in the body of another animal that is immune to this infection. For this the serum of an immune animal is used. As this method was employed for cowpox, tetanus, diphtheria, and other infections, we have tested its value for tuberculosis. We have submitted our animals to injections of serum from immune animals, and have developed considerable antitoxic power in their blood, at the same time we uphold the evident action of new serum, on the vitality of the bacilli, and the resistance of the animals to the intravenous injections of virulent bacilli.

Tubercle bacilli introduced beneath the skin of those animals immunized by the serum were destroyed with singular rapidity.

We have made the same experiments with injections in a healthy man. Naturally it is not possible for us to verify their efficacy by means of the virulent bacilli test, as in animals. For this reason we have resorted to different criteria, that is to say to investigations upon the antitoxic action, and the agglutinating power. We have found that our treatment was followed by a considerable increase of agglutinating power (some samples showing as high as 1 to 30 or 1 to 50) as well as of antitoxic power: otherwise the blood of these individuals affected the vitality of the bacilli.

We have also proof that injections of serum of immune animals into a healthy man cause the appearance in his body of specific elements of defense, of high degree, which furnishes us a very plausible reason for thinking that we have by these means, furnished our subject with defensive and immunizing materials.

We have had some direct proof with individuals suffering from pulmonary tuberculosis. A tuberculous patient is really comparable to an animal inoculated with tuberculosis, as the one as well as the other has bacilli in its body; in the one infection is caused by ambient conditions, in the other by the experimenter. We have injected the serum of immune animals into a man that was undoubtedly tuberculous, and at the same time that we caused the arrest of the tuberculous processes we developed in him defensive materials which we could measure exactly according to my method.

In the subjects that I have cured in a lasting manner the serum has evidently played the rôle of immunization along with its therapeutic action, for if not we would soon have seen a reinfection established in an organic soil that had lost its defensive powers, or the capacity to produce them. This is a fact toward which we have not yet directed our attention, but which, however, deserves to be seriously taken into consideration. For, owing to the great diffusion of the bacilli of tuberculosis, it must be admitted that when a subject cured of tuberculosis does not take necessary precautions, the possibility of his not contracting a new infection can only depend upon a modification of the organic soil which had become refractory to tuberculosis. Otherwise reinfection would be inevitable. We know several such individuals, treated with serum injections, who have been cured of tuberculosis for ten years, and who come from time to time to be under the control of our clinic.

The number of patients treated with the serum of immune animals and those of physicians who have in some degree applied this treatment to their clients, and continue to use it, is already so large that it is impossible to give complete statistics. But all the physicians who have inoculated tuberculous patients with the serum of immune animals have some cases that have been immune for several years. We, therefore, feel that we are right in admitting that injections of the serum of immune animals can develop in man a certain degree of immunity.

As a striking instance of this I will quote the case of a tuberculous family under my observation in the Polyclinic.

In the family, the mother who is a healthy woman, had a brother and two sisters who died of tuberculosis. The relatives of the father were healthy. Twelve children were born of this union, of which one died at the age of three, of diphtheria. All the other eleven were tuberculous, four dying before the family came to my

clinic. The remaining seven children who showed different degrees of pulmonary tuberculosis were treated by means of progressive antitoxin injections; that is to say they were possibly rendered immune. To-day they are in excellent health and have no symptoms of any trouble in the respiratory tracts. Their immunity has lasted for ten years, during which time they have been obliged to work under miserable hygienic conditions, and to be exposed to the weather. Their case is significant on account of the number of sick ones in the family to which they belonged.

Another method of passive immunization consists in introducing the defensive materials contained in the serum directly into the digestive tract, instead of injecting them directly into the body.

This method has not yet received the approval of all investigators, who hold that the defensive materials are altered and not assimilated in the gastro-intestinal tract. Setting aside all the doctrinal wisdom invoked to uphold this view, it is a fact that for certain infections the introduction of defensive materials into the stomach is possible. Sclavo, an investigator and experimenter of high renown, has proved this for diphtheritic antitoxins, and Mercatelli for the pest vaccine.

In my Institution and clinic, we have carried on such researches for five years, and have announced in preliminary reports what we can now affirm, viz., that we have verified in man as well as animals, what Sclavo observed for diphtheria. The immunizing materials pass into the circulation and have an analogous action to that of the serum injections.

We have in our Institute some rabbits that were fed on certain quantities of blood taken from immune animals and that after a month showed to a high degree both antitoxin and agglutinating power.

Behring recently expressed his hope, in Vienna, that it might be possible to immunize animals by feeding them with the milk of cows immune to tuberculosis, and announced that he was going to make investigations to see whether the antituberculous material passed into the milk and could be assimilated by those who drank it. We have studied this question before him. We can state on the one hand that the defensive materials of the cow that is immune to tuberculosis do pass into the milk, but in small quantities only, but on the other hand that these materials, as I have just said, when introduced into the digestive tract are absorbed and exert a protective action in the organism of animals, and even of adult men. Also, it is quite possible that these immunizing materials get into the human body by means of milk.

But my spirit is burdened with the desire to attain even a higher end, viz., the artificial creation of active immunization in man, his vaccination against tuberculosis, just as it is practised for smallpox, in such a way that it will cause autoimmunization. For active immunizations are preferable to passive ones, as they cause the organism to play a much greater part in the process of immunization; and its reaction to the contact of morbid elements created by the defensive materials is more stable and lasting in the human organism.

I have examined the question from the clinical standpoint, and I have studied it experimentally. From the clinical standpoint I will call your attention to an important fact that deserves serious examination. When a man develops in any part of his body whatsoever a localized focus of tuberculosis, if this focus heals the man remains, as a rule, immune to tuberculosis. It is rare, for example to see any other tuberculous focus appear; after a surgical operation for tuberculosis is performed. In families in which tuberculosis is prevalent we see subjects that have been cured of tuberculous arthropathies living in a very good state of health. Those who listen to me will be convinced of this if they but call to mind cases in their own clientele. They will find it the same for those who have suffered from cutaneous tuberculosis. These cases of external tuberculosis are very valuable for our demonstration, for they lend themselves to exact diagnosis and to exact establishment of complete cure, for, of course, cure must be complete if the case is to be of real value.

But one may also observe similar cases in visceral tuberculosis. There are many patients who have had attacks of peritoneal tuberculosis and who once cured have never had another focus of tuberculosis. The same observation holds good for tuberculosis of the pleura and lungs.

When a person is surely and completely cured of a pulmonary tuberculous focus, with the formation of a sclerotic tract in the area of a previous infection, he generally remains thereafter permanently unsusceptible to tuberculosis.

Similar facts which we obtain from the clinical histories show us that tuberculous subjects may after complete cure, remain immune against tuberculosis. I say immune, for as I have said before, as I like often to repeat, an organic soil that has once contracted tuberculosis, must necessarily be exposed to new infection if it does not undergo a (complete) transformation.

This clinical consensus and the positive fact that I demonstrated eight years ago, and have confirmed by successive work, viz., the possibility of definitely and surely immunizing animals against tuberculosis, have formed the starting point of my studies on the vaccination of men.

I have first outlined in my method all processes of immunization founded on the inoculation of any kind whatever, of living bacilli in the organism. Injections of cultures in the veins, however attenuated—such as employed by Behring for calves could never be used for man. And it is false that active immunization is only possible by means of injections of living cultures. According to this maxim that Behring has recently pronounced we would be forced from the start

to preclude all possibility of obtaining auto-immunization in man.

But, happily, I believe that it will be possible to obtain this result by means of inoffensive treatment. The first proofs of active immunization in man were furnished to me by the injections of tuberculous poisons.

I have already spoken to you of these experiments. In a healthy man these injections cause the formation of antitoxins, and of agglutinizing materials, and correspond exactly to the effect that Koch noted recently, in connection with the immunizing action of injections of tuberculin in man. As long ago as 1891, apropos of the old tuberculin, I maintained that its action might, perhaps, bear some relation to the production of defensive materials in the blood; and my successive experiments, as well as those of a great many observers, have proved the truth of this assertion.

In some tuberculous patients, after having effected a cure by means of the serum of immune animals, I have practised successively injections of tuberculin and serum, then only tuberculin, and have obtained confirmatory results. For subjects treated in this way do not show, at the end of seven years any sign of tuberculosis, and continue to keep well, although living always in their habitual ways. Among others is a physician who continues to follow his profession, which exposes him continually to new infection.

I have wished, however, to produce immunization in another way, and I am applying myself to the solution of the following problem: How to obtain immunization by producing a circumscribed focus of tuberculosis on the surface of the body.

The principal difficulty consists in choosing a suitable material for immunization, for the point is to obtain everything that pertains to living bacteria without using the living bacteria themselves; we must, in short, find a material of inoculation with which there would be not even the most remote possible danger of causing tuberculous infection.

After many trials and experiments I have succeeded at last in preparing a material, which, all danger of infection excluded—will cause, when inoculated under the skin, a tuberculous phlegmon. By means of these inoculations, we possess the possibility of establishing the production of immunizing resources in animals. For, naturally, it is on animals that we have made our first experiments of immunization according to the new method.

I can state to you now, that the inoculations have determined the production of antitoxic, bacteriolytic and agglutinating materials, and have immunized my animals to the point of rendering them insensible to intravenous injections of virulent cultures that inevitably killed the controls, as I was able to prove even for rabbits.

Being convinced, gentlemen, that the treatment is innocuous, I have begun to use it on men. It is clear that in their cases, we cannot practise crucial experiments as we do for animals, that is to say, the injection into the veins of virulent cultures of bacilli in order to get incontestable proof of their immunity. But the blood of subjects thus treated, has acquired a high degree of agglutinizing power, and at the same time an abundant leucocytosis has resulted; that is to say, the blood of man has shown the same modifications as that of animals.

I have made these inoculations on one of the limbs, settling at last definitely upon the arm. At the point of injection there appears a development of a small circumscribed area of tuberculous ulcer with suppuration that is entirely sterile; the temperature runs a fever course for two or three days as a rule; and then everything is over.

This, gentlemen, is what I have done along this line.

Certainly the road along which we must travel is still long; but after all that I have seen with my own eyes, I have the right to be convinced that if we can render animals immune, we can in the future render man immune. I wish that there might still remain for me enough of life to see this conquest of science brought to an end; but the way is open, and by me or by others, the end will be obtained.

A vision of this day is clearly pictured in my thoughts, and it will be remembered in future that it was to the friendly hospitality of Spain, in her beautiful capital, Madrid, that the dawn was announced.

---

## TUBERCULOSIS IN THE TENEMENTS; A NEW USE FOR FIRE-ESCAPES.

BY ALFRED MEYER, M.D.,
OF NEW YORK:
ATTENDING PHYSICIAN MOUNT SINAI HOSPITAL.

The outrageous insinuations made by Lady Mary Wortley Montague against the medical profession in 1717 surely would be impossible to-day. She wrote at that time regarding a useful remedy for a prevailing epidemic: "I should not fail to write to some of the doctors very particularly about it, if I knew any of them that I thought had virtue enough to destroy such a considerable branch of their revenue for the good of mankind. But that distemper is too beneficial to them not to expose to all their resentment the hardy wight that should undertake to put an end to it."

Everybody who is familiar with the world's antituberculosis work of the past few years knows how large has been the share of physicians in the attempt to limit the spread of the disease, and, if possible, to wipe it out from the category of human ailments. It is due to the initiative of medical men that in nearly every civilized land of the world, sanatoria have been established in increasing numbers for the cure and sanitary education of those suffering from pulmonary tuberculosis; the propaganda for state and municipal aid has been kept up by them, they have served on committees for kings and governors without compen-

sation, to further the good work; and they have pointed with pride to the gradual but steady reduction in the death-rate from this disease.

In New York City there was a reduction of 10 per cent. last year in spite of the increase of population. It would be hard to find a more splendid

Pulmonary Tuberculosis Successfully Treated on the Fire-Escape of a New York Tenement House. Near View.

example of altruistic effort, and the sneers of Lady Montague would be strikingly out of place to-day. Yet the vastness of the numbers to be provided for in sanatoria has always been a great obstacle in the work; and another difficulty has been the overestimation of the value of particular climates and altitudes, and the underestimation of fresh air *per se;* the overestimation of the value of medicines and the underestimation of the value of light, food, invigorating baths, sponging and continual medical supervision. In recent years, however, the eyes of the medical profession have been gradually opened to the truth that a large proportion of cures may be effected without expatriation, without exhausting journeys, without great traveling expense, without breaking up of families, without a complete isolation from those who are dear, without the brooding home-sickness that comes with the rupture of domestic ties and banishment to distant lands and strangers. And the corollary of this position is the one that finally each country can solve its own tuberculosis problem at home,—this being true even of the smaller political units, such as counties and cities.

Now, in New York city we have a feature in tenement-house construction which appears to me to open up very large possibilities for the successful outdoor treatment of pulmonary tuberculosis among the poor—particularly in such cases as are forbidden exercise on account of fever. This feature is the fire-escape. Fire-escapes are almost universal in tenement and apartment houses, they are very accessible for the weakest patient, they are large enough to permit the placing of a reclining chair or couch, they are convenient for such supervision and attendance on the part of the family as may be required by the patient, and many of them have abundant air and light, varying of course, with the style of tenement, the floor and the direction in which it faces. On the other hand, the fire-escapes are not open to the objection raised (among others) against the roofs, of smoke and gas from the chimneys: they are sheltered in many directions from the wind, or are easily sheltered from wind, rain, and snow by such simple contrivances as umbrellas, screens, or bits of awning.

At the recent meeting of the New York State Conference of Charities and Correction, I advocated the more general use by the medical profession of the fire-escape in the treatment of such cases of pulmonary tuberculosis as could not be accommodated at sanatoria, or for one reason or another did not wish to go to them, or pending their admission to them. Pictures were shown of a consumptive girl of fourteen years taking the outdoor-rest-cure-treatment on the fire-escape of the third floor of a tenement house in the neighborhood of First Avenue and Eighth Street, New York. The photograph was taken on Dec. 21, 1901, the temperature of the air at the time being 24° above zero. Although it was the shortest day of the year the little patient was able to spend about four and a half hours on the escape that day. She first came under my observation early in November, 1901, with extensive tuberculous disease of the left lung of about four months duration—high fever, rapid pulse (140), albuminuria (5 per

Pulmonary Tuberculosis Successfully Treated on the Fire-Escape of a New York Tenement House. Distant View.

cent.), diazo reaction and indications generally of a rapidly fatal issue. The fire-escape treatment was faithfully adhered to all winter, the number of hours spent there increased as the days lengthened, and the neighbors gradually became accustomed to the strange sight of the sick girl lying outdoors in the cold, all bundled up, with only

eyes, nose and mouth showing. The result has been extremely gratifying. The return of appetite and strength, the gain in weight, the gradual reduction and disappearance of fever and cough, the disappearance of complications, all betoken the value of the régime followed under surroundings usually condemned as portending failure. Nor is this an isolated case, but it is illustrative of others seen by me since then in which a similar régime was followed by similar results. This method of treatment is open to large numbers of physicians and patients in the city. It requires perseverance on the part of both physician and patient and the intelligent cooperation of both; above all, it requires a complete emancipation of the tenement-house population from the old idea that pulmonary tuberculosis is a catarrhal disease that compels the patient to avoid cold and exposure, and on the other hand, it requires the education of this same class in the modern view of infection and the advantages to be obtained, even at home, from a very free exposure to air.

There is one difficulty in the way of the general adoption of the fire-escape plan of treatment, but perhaps, after all, this is no real difficulty. I refer to Section 113 of the Building Code of the City of New York, forbidding the placing of "any incumbrance of any kind whatsoever before or upon any fire-escape, balcony or ladder" and providing a penalty for any violation of the same. Every New Yorker knows that this ordinance is more honored in the breach than in the observance. I believe the Fire Department expects the Building Department to enforce its provisions, and the Building Department in turn expects such action from the Police Department.* Public opinion will, I venture to predict, sustain none of them if the ordinance is enforced against those who in their fight for life are making of the fire-escape a real life-saving contrivance.

801 Madison Avenue.

## SOCIETIES FOR THE PREVENTION OF THE SPREAD OF TUBERCULOSIS. THE NECESSITY OF SUCH ORGANIZATIONS AND THE WORK TO BE ACCOMPLISHED BY THEM.†

BY F. M. POTTENGER, PH.M., M.D.,

OF LOS ANGELES, CAL.:

PRESIDENT OF THE SOUTHERN CALIFORNIA ANTI-TUBERCULOSIS LEAGUE; CORRESPONDING MEMBER OF THE INTERNATIONAL CENTRAL-BUREAU FOR THE PREVENTION OF CONSUMPTION; MEMBER OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION; ETC.

With this meeting we begin the organized effort to prevent the spread of tuberculosis in Southern California. That there is need for such a movement no one can deny. Whether or not the society shall accomplish its purpose will depend very much upon the interest and earnestness manifested by the board of directors, since by the provisions of the by-laws of the society its management is largely entrusted to our care; so let the interest manifested be commensurate with the importance of the work to be accomplished.

The tuberculosis problem is one that should interest every one. From time immemorial this disease has been the curse of mankind. In various countries it is accountable for from one-tenth to one-fourth of the total death-rate. Few are the families that have not felt its blighting touch and scarcely can one be found who has not a friend or dear one afflicted with this disease.

Such has been the condition of affairs throughout the ages; yet little has been done to prevent the disease until recent years. England began the movement sixty years ago by passing acts providing for sanitary homes and workshops, believing that there was a relationship between cases of tuberculosis and the bad hygienic condition found in the usual home and shop of the worker. In consequence of this wholesome legislation, the number of cases of the disease decreased. It was not, however, until Koch had discovered the bacillary cause of the disease and proven that it was a disease communicated from one person to another that it was widely believed that it could be prevented.

Few diseases of bacillary origin offer greater hope of an ultimate eradication than tuberculosis. The very nature of the disease favors this. While it is communicated directly from man to man, yet, if ordinary precautions are taken, infection rarely occurs. This is the evidence which inspires us with hope and shows us that tuberculosis is a preventable disease. Another important factor is the slowness with which the disease develops, months and often years intervening between the inoculation and the death of the patient; in fact, far more people become infected, and recover from the disease than die of it. Autopsies show healed foci in the lungs of from one-third to more than one-half of bodies examined. The great majority of these are cured without knowing that they were ever tuberculous. Of those cases in which the disease is diagnosed, at least 50 per cent. in the first stage can be cured by appropriate treatment; and a smaller number in the advanced stages. This gives us our second hope in fighting tuberculosis. It would be very hard to carry on a fight when it were known to be on the losing side; but, in our fight with tuberculosis, we have much to encourage us *for we are dealing with a disease which is both preventable and curable.*

Such being the case, why is it not prevented and why is it not oftener cured? Why is a preventable and curable disease allowed to destroy more than a hundred thousand lives in the United States yearly? This can only be accounted for by ignorance of the facts on the part of the many and apathy on the part of those who know.

Experimental evidence and clinical experience tell us that there are two elements in infection; first, the bacillus, and second, a susceptible individual. Unless both of these elements be present, infection is not likely to occur. We further know that the bacillus comes in every instance

* Since writing the above I have learned that the enforcement of the law, so far as it relates to tenements, is lodged with the Tenement House Department.

† Read before the first meeting of the Board of Directors of the Southern California Anti-Tuberculosis League, Jan. 15, 1903.

from some previous case of tuberculosis, and that susceptibility is due to those things which lower vitality such as living in badly ventilated and poorly lighted houses; overcrowding; living on insufficient and improper food; various diseases; and the abuse of alcoholic liquors. Any comprehensive scheme of prevention should take into consideration all of these elements.

It is gratifying to know that wherever preventive measures have been undertaken, whether they have been directed to the destruction of sputum and other bacillus-bearing discharges, to the prevention of sale and consumption of infected food, or to the elevation of the plane of living of the people, they have been rewarded by a decrease in the death-rate from tuberculosis. A glance at statistics is most instructive to us who are about to take up this work. The following table gives the prevalence of this disease in several of the large cities of Europe, as based upon the number of deaths per 10,000 living inhabitants:

| | | |
|---|---|---|
| Moscow | 45.68 | per 10,000 inhabitants. |
| St. Petersburg | 44.10 | per 10,000 inhabitants. |
| Vienna | 42.72 | per 10,000 inhabitants. |
| Paris | 38.70 | per 10,000 inhabitants. |
| Berlin | 23.06 | per 10,000 inhabitants. |
| Rome | 18.85 | per 10,000 inhabitants. |
| London | 17.68 | per 10,000 inhabitants. |

In Russia very little has been done; in Vienna, but little more, while in Berlin and London active measures have been taken to lessen the spread of the disease, especially in the way of better houses for the poor and better living for them; and in Berlin especially, precautions are taken to prevent infection through milk and meat.

A review of what is being done in other parts of the world will perhaps not be out of place here; so I will try to tell you what other nations are doing as best I can from the data which I have at hand.

As mentioned above, England is really the pioneer in this movement. In 1836 she passed an act providing for the construction of hygienic houses. This act has been followed by nearly a dozen more, all directed to the establishment of better workshops and better houses for the workers. Not only was England the first to recognize the necessity of better hygiene in the homes, but she was also the first nation to establish hospitals for those suffering from tuberculous diseases. The oldest of these is the Royal Seabathing Infirmary for Scrofula in Kent County, founded in 1791. Following this was the Royal Hospital for Diseases of the Chest, in London, founded in 1814. The Brompton, the most important of the English hospitals, was founded in 1841.

It is strange to say that, while England was the first nation to establish hospitals for the care of the consumptive, she has been slow in taking up the cause of the early cases and establishing sanatoria where they may have the opportunity and care necessary to regain health. This, however, she is now doing. In 1899 the National Association for the Prevention of Consumption and other forms of Tuberculosis was formed under the presidency of the Prince of Wales. The patronage of the Prince of Wales gave to this movement the sanction of the government; consequently, it has had a steady growth. Many subordinate branches have been established, pamphlets of instruction have been circulated; and the people have been enlightened on this important question.

In Germany, a congress was held in the year 1899 to consider tuberculosis, as a disease of the masses, and how to combat it. This congress popularized the subject of "sanatoria for the poor." Since then the number of sanatoria has been constantly growing, and now there are nearly one hundred institutions where the curable cases of tuberculosis may go to regain their health. One thing that has helped the work of construction of sanatoria in Germany is the insurance law which requires every laborer who is earning less than 800 marks a year to be insured against accident, old age and disease. The insurance companies have learned that it is to their advantage to have tuberculosis diagnosed in its incipiency and to provide sanatoria for those afflicted where they can be cured in a short time. The demand of these insurance companies has called out the best diagnostic ability of the German medical fraternity and they are now diagnosing a very large proportion of the cases of tuberculosis before bacilli appear in the sputum.

France has been slow to establish sanatoria for the tuberculous adult but she has set the world a good example of what can be done in the treatment of scrofulous children. Throughout the nation there are several of these institutions near the large cities and also several on the sea coast. In these, about 50 per cent. of the children are cured. In Paris there are about forty dispensaries for the treatment of children where several hundred thousand children, suffering principally from scrofula and rickets, are treated annually. France has also given us another important lesson in dealing with the tuberculosis problem by establishing dispensaries in the centers of population. In some of these many hundreds of afflicted are helped annually. Not only is medical aid furnished, but in some of them food and clothing are given and a nurse or attendant is delegated to go and see that the home life is healthful and sanitary. In this way not only the afflicted one is helped, but the entire family is instructed in hygenic living and also in the manner of preventing contagion. In the city of Lille, such a dispensary is in operation. In this city it is estimated that there are about 6,000 persons suffering from tuberculosis and from 1,000 to 1,200 dying annually, although there are only about 220,000 people in the city. The great good that such dispensaries can do in a city with so large a proportion of its population tuberculous must be evident to all.

Other European countries have also taken active measures to check the progress of tubercu-

losis, but these great nations represent the best that has been done.

In the United States we have been somewhat slow in taking up the movement. This is due to several things. In the first place, we have no National Tuberculosis Commission, to take up the matter and, secondly, we have no royalty to popularize the movement. Whatever is done here must be done through private initiative hence it is sure to be slow.

The first Society for the Prevention of Tuberculosis in the United States was formed in Pennsylvania in 1891. Since then, Maine, Ohio, Illinois and Missouri have formed State societies; the cities of Buffalo and Cleveland have local societies; New York has a Tuberculosis Committee, and California comes next in the list with The Southern California Anti-Tuberculosis League. We should be proud of the distinction of being so near the front in this great work.

This paper would not be complete without mentioning the Central International Bureau for the Prevention of Consumption. The Central Bureau is composed of members from all nations that will affiliate in the international crusade against tuberculosis. The headquarters of the committee is in Berlin; and, at stated intervals, there will be meetings held for the consideration of the progress of the movement and for the suggestion of better methods. Corresponding members throughout the world keep the committee posted as to what is being done in the various countries and the Central Bureau on the other hand keeps the various members in touch with the general progress. It is expected that the members of the International Bureau will keep themselves posted as to the best methods of combating tuberculosis and that they will be centers for the distribution of facts for their respective countries. In this way, it is hoped that the Anti-Tuberculosis Crusade will take an international aspect, instead of each nation and each State being isolated in its efforts. This organization was formed in the year 1902 and held its first meeting in October of the same year. It is to be hoped that the committee will receive a generous support and that its work will greatly aid in the prevention of tuberculosis.

The problems before the Anti-Tuberculosis League of Southern California are the same as those of any other society which is trying to prevent tuberculosis. The disease is the same wherever found, produced by the same causes and prevented by the same measures.

Here in Southern California, however, we have the problem intensified; for we have not only the cases which develop here but also those which come from without our State, that they may secure the blessings of our climate. To offset this more intense problem, we have an eternal sunshine and aseptic air which renders the dangers from contagion much less than would be the case in a less favorable climate.

Koch is authority for the statement that sunlight will kill tubercle bacilli in from a few minutes to a few hours and Solly says that a room which has been occupied by a tuberculous patient or which has been infected by bacillary sputum may be safely occupied at the end of three to five weeks, if air which has been sunned has been admitted to it. So we see that Nature has been very kind to us in giving us this eternal sunshine and that she has protected us in a manner that is not common to many sections of the world. These facts show us that we may help to prevent infection by making use of sunshine and fresh air in our homes.

Cornet, and later, Coates, under the direction of Delépine, made experiments to determine the infectiousness of rooms which had been occupied by tuberculous patients. The results proved that where the rooms were well lighted and well ventilated the danger was much less than in those poorly lightly and badly ventilated, even though the cubic space per inhabitant were greater in the latter; also, that the dust in houses occupied by tuberculous individuals, who are careless about the disposal of their sputum, is dangerous, while the dust from houses of the same degree of cleanliness not occupied by tuberculous individuals is not infectious.

These experiments taken in connection with those made from the dust collected from the rooms of sanatoria when sanitary precautions are taken and which proved innocuous in nearly every instance; and, also, when considered in connection with the fact that during the past 20 years since the discovery of the bacillus many thousand patients have been treated in institutions and yet neither a nurse nor attendant has been infected in those whose history I have at hand, shows that carelessness is the prime cause of the spread of infection and also that where care is taken there is practically no danger.

According to the public health reports for the year ending December 31, 1900, there were in 18 cities and towns in the State of California, having an estimated population of 675,000, 2,000 deaths from tuberculosis. That is, 17.6 per cent. of the deaths were assigned to tuberculosis, making a death-rate from tuberculosis of 2.9 per thousand of inhabitants. Eight of these cities and towns were in Southern California representing an estimated population of 147,479. In these, tuberculosis caused 23 per cent. of the deaths, making a death-rate from tuberculosis of 3.5 per thousand of inhabitants. When we consider the thousands of tuberculous individuals who come to Southern California annually and especially the number who come to die, and that these statistics include only the centers of population where the death-rate is the greatest, we must congratulate ourselves that our rate per thousand inhabitants is not higher. That it is not is not due to any special precautions that are taken, but must be attributed to the favorableness of our climate. Here people can be in the sunshine three hundred days in the year and even if they are not fresh air fiends, they can have their houses open to the free entrance of air most of the days. This death-

rate, however, is far too high. By proper precautions we can reduce it. We can save the lives of many who come from without our State, and by proper regulations reduce the number of native cases, and in this way lower the rate. How to do this is one of the problems before us.

The work of our league should be carried out along several lines. In the first place we should educate the people to the fact that tuberculosis is communicable. We should teach them just where the danger lies and that if the bacillus-bearing discharges, of which the sputum is the chief, and in most cases perhaps the only one, are carefully destroyed. There is no danger from the tuberculous individual. While we must insist on the enforcement of sanitary laws, we must avoid creating in the minds of the people an unnecessary fear which will work undue hardships on those afflicted. Nowhere can it be said with greater justice that "a little learning maketh mad," for, those who have learned that tuberculosis is a communicable disease and have learned nothing more have become frightened and are associating, in their minds, tuberculosis with such diseases as smallpox. We must emphasize with equal if not greater care that tuberculosis is preventable. We must furthermore teach them how to prevent it, give full and explicit directions for the afflicted and also for those who must care for them. The necessity of sunlight and fresh air should be emphasized.

Sanitary laws relative to the prevention of infection, such as those forbidding expectoration in public places, providing for the notification of tuberculous cases and the disinfection of rooms occupied by tuberculous individuals before being reoccupied should be passed. In order to facilitate and encourage early diagnosis in the cases among the poor, free examinations of sputum should be made for those who are too poor to pay for same. Laws regulating the height of buildings, the height of ceilings, the ventilation of workshops and tenement houses, prohibiting the construction of unsanitary dwellings and overcrowding, would do much to prevent that lowered vitality which facilitates infection and would offer less opportunity for the bacilli to thrive.

Lest I be misunderstood, I would like to offer a word on the subject of notification before passing. There is objection raised to this on the part of some, believing that it will work as a quarantine. Not so. It is only intended that the case be reported that the health officer may see that precautions are carried out. Perhaps, until public opinion is educated, it would be better to have notification optional. No one but the attending physician and the health officer need know that the individual is tuberculous. It should work in favor of the afflicted instead of against him.

Another important field of work for our league is in caring for the afflicted poor. This is a necessary measure from the standpoint of prevention and desirable from the standpoint of the humanitarian. As long as the poverty-stricken tuberculous individual is compelled to care for himself, he will be forced to occupy unsanitary quarters and will scatter infection about him either because of ignorance or because of a spirit of apathy. Since each patient on an average infects one new one, and each careless one may infect several, it can be plainly seen that the care of the helpless poor bears a very important relation to the problem of prevention of tuberculosis; and, since hospital facilities are provided for those suffering from other diseases, it is but just that they should be provided for these.

The Anti-Tuberculosis League could perform for the tuberculous poor an act of mercy, render society a noble service and itself a great honor, if through its efforts there should be established in our midst a system of dispensaries in the cities where those afflicted could come for advice and where those who suspect the disease could be examined while they are in a curable stage; and further, if through its agency there should be provided sanatoria for those who are curable and hospitals for those in the advanced stage.

Such is the work that has been done by organizations of similar aim; such is the work that I hope will be accomplished by ours. We may have to work slowly, for we cannot go faster than public opinion; but, by the distribution of carefully written pamphlets, by the delivery of thoughtfully prepared lectures and by the judicious use of the public press, I believe it is possible to secure a hearty cooperation on the part of the people.

---

## THE SANATORIUM TREATMENT OF TUBERCULOSIS.*

BY HERBERT MAXON KING, M.D.,
OF LIBERTY, N. Y.;
PHYSICIAN IN CHARGE LOOMIS SANATORIUM, LIBERTY, N. Y.

WHEN an appeal is made to the family physician for his counsel as to the best and most promising course to follow as a means of relief or cure in a case of tuberculosis, the question with which he is confronted is by no means so simple as at first appears. Circumstances—varied as individual cases—must be carefully taken into consideration, and will, in each instance to a great extent determine the choice of alternatives which offers. Of these, broadly speaking, there are three: (1) The patient may be kept at home and given the best which his means will permit in the way of care and treatment; (2) he may be sent to an open health resort, where it must be left largely to his own judgment and financial resources as to his personal environment and his medical supervision; and (3) he may be placed in an institution, especially adapted to the care of this class of sufferers.

The chief factors which will have to be considered in reaching a decision in any given case are of course two: (*a*) The extent to which the disease has advanced including the individual

* Read in abstract by invitation before the New York Academy of Medicine at a symposium on Tuberculosis, February 5, 1903.

resistance of the patient, and (*b*) the financial resources of the patient.

Within the limitations of the subject which has been assigned to me, a discussion of the many phases of the question both as to their relative merits in a given case and as to their more general aspects as applied to the class of tuberculosis invalids as a whole would be out of place. It is sufficient to say that with some experience and discrimination each case will, by its own characteristic peculiarities determine the class to which it belongs and the treatment which is best to be accorded. Confusion as to choice of alternatives cannot easily arise when once all the facts are known. The difficulty seems to be that too often advice is given without a sufficient inquiry into the facts, with the result that in every open health resort, many forlorn individuals without sufficient means or sufficient intelligence to secure the rest and medical supervision, which in certain stages of the disease are so imperatively essential, die each year who would have had a much better chance of arrest or cure of their disease in a properly conducted sanatorium. While, on the other hand, in every sanatorium may be found a certain proportion of cases which would be as well or better off in their own homes.

As an outcome of the very general agitation of the subject during the past few years, such mistakes are fortunately becoming more rare and the special functions and inestimable advantages of sanatorium treatment are for like reason much more generally recognized by both physicians and their patients. Brehmer began his memorable work in Gerbersdorf in 1859 and, as every one interested in the subject knows, after contending with more or less bitter opposition for several years, succeeded in demonstrating the value of the fundamental principles which governed his methods to the satisfaction of many of his most severe critics. The sanatorium at Falkenstein, to which Knopf refers as the "Mecca of phthisiotherapeutics," was established through the efforts of his ex-patient and pupil, Detweiler, in 1876. From these beginnings the growth of the sanatorium idea in Germany and Switzerland was constant, though for reasons which will follow presently, much more tardy than would otherwise have been the case with a medical innovation possessing the demonstrable advantages of the sanatorium.

In this country the acknowledged pioneer in Brehmer's methods is Dr. Trudeau, who established the Adirondack Cottage Sanitarium in 1884 and whose splendid labors in this field have gone far toward educating the medical profession in America to a recognition of the advantages of special institutional care of the phthisical patient.

When in 1882 Koch announced his isolation of the tubercle bacillus, attention was for the time almost completely diverted from the slow but rational open air therapeutics of the sanatorium to the golden hope of finding a "short cut" to health in a specific. And to this circumstance, I think, may be attributed the retarded development of Brehmer's ideas. When it was finally understood, however, that curative or immunizing agents for tuberculosis were not to be attained, if at all, until, so to speak, a vast deal of new country had been explored, that antitoxic and bactericidal bodies were not to be available for clinical purposes except by the slow process of scientific evolution—attention of the clinician again turned to the methods which so far had alone given satisfactory results in the treatment of the consumptive. This subject then, notwithstanding the over abundance of literature which recent discussion has brought forth, can not yet fail to be of interest to the practitioner of medicine to whom the question as to how to advise his phthisical patient is constantly arising.

Before entering into the details of the so-called sanatorium treatment of tuberculosis, a few general observations relative to the subject must be first considered. It must be remembered that there can be no universal rules as applying to all cases alike, therefore in describing a routine practice either as pertaining to rules of admission, methods of treatment or to the administration of sanatoria themselves, it must be left to reasonable inference to modify and adapt them to the particular individual in each case. For instance as to the location of the institution, both in its relation to climatic advantages and public convenience. Experience bears out the truth of the saying that while no climate is specific for tuberculosis many climates are useful. Indeed, so long as the essentials of Brehmer's methods are secured, the location of the institution in which they are carried out may be safely left to expediency. The first of these essentials is unquestionably pure air, and plenty of it, and as it is obvious that this important desideratum cannot be secured within the immediate limits of a thickly populated city, the site for a sanatorium should be sought elsewhere. Nevertheless it must not be forgotten that excellent results are obtained in two sanatoria situated within a radius of three miles from the center of the city of Edinburgh, and I am informed that the "sanatorium wards" of Brompton Hospital yield amazingly good results, notwithstanding that the institution is within the limits of a thickly populated London suburb, and what is still more important that but a very small proportion of its patients are received in the earlier stages of the disease. L'Hopital Boucicaut, as you know, is within the fortifications of the city of Paris, yet in the pavilions set aside for phthisical patients there, it is remarkable what is done toward the arrest of the disease. It must be admitted, therefore, that sanatorium methods may, to a certain extent, be successfully carried out even in towns, while at the same time no one will deny that a location remote from centers of population is much to be preferred.

Wards and pavilions for the reception and sanatorium treatment of phthisical patients in connection with town hospitals have recently come to be recognized as a crying need, and while

such can not for apparent reasons be considered ideal institutions they are nevertheless the best expedients which the urgent necessities of the situation can suggest, and after all much can undoubtedly be accomplished in them.

Again climatic influence as a feature of sanatorium treatment should be here considered. The subject of climatoloy in relation to tuberculosis is, I am aware, not within the province of this paper and is elsewhere fully and ably discussed. It is, therefore, sufficient for present purposes to limit my remarks to the question as it relates to sanatorium treatment alone. That there is a certain percentage value in altitude in phthisis I am convinced, but just what that percentage is, has never so far as I know been satisfactorily worked out. It is probably not large and when applied to all cases as they occur in practice, *i.e.*, early and advanced stages alike, is entirely wiped out. Unquestionably sanatoria situated in the high altitudes, *e.g.*, from 5,000 to 15,000 feet are far more limited in their scope of usefulness than is the case with those at the more moderate elevations. I have heard it remarked, on the other hand, by one whose broad experience gives authority to the statement that no institution intended for the treatment of patients in the early stages of phthisis should be located at less than 1,000 feet above tidewater, and from my own experience, I am much inclined to agree with him.

The advantages to be derived from altitude may be summed up in (*a*) the rarefication of the atmosphere and the consequently lessened barometric pressure, (*b*) the reduced humidity, (*c*) the ascepticity of the respired air and (*d*) the diathermancy. Now, in a method of treatment in which life in the open air plays such an important part these advantages demand thoughtful consideration.

The question of direct sunlight and wind is still an open one. Recent observations seem to show that diffused sunlight, such as obtains on cloudy days, has in tuberculosis all the therapeutic advantages of the direct sun's rays. For my own part, I believe that in this as in many other questions in phthisiotherapeutics, adherence to extreme views is a dangerous policy. Certainly a considerable amount of sunshine is desirable in sanatorium treatment, while at the same time it is remarkable that during the winter months in our climate when the number of cloudy days exceeds by far those of the summer months, sanatorium patients make their most rapid and substantial gains. The same is true in Davos, St. Moritz and Arosa. It is possible, however, that other causes enter in to produce this result.

In spite of contrary opinions on the part of many authorities I am in favor of wind in a resort for phthisical patients, protection of the individual from direct exposure is easily accomplished by shelters and the purifying and invigorating effects of strong, cool and dry wind in a pure air can not be overestimated. It secures ventilation of buildings and apartments much better than any artificial device can do and when patients are constantly living in the open air, as in a sanatorium. I have not remarked that it ever increases liability to colds or aggravates catarrhal conditions of the respiratory mucous membrane, which I believe are the chief objections which have been brought against it.

In short the location for a sanatorium should be sought in a climate which need be neither very cold nor very warm—it should be sufficiently dry to prevent the depressing and enervating effects of excessive humidity, yet not so dry as to permit dust suspension in the air. It should be stimulating and possess atmospheric conditions which favor the development of nervous and muscular vigor and the altitude should whenever possible exceed 1,000 feet.

The two fundamental principles of sanatorium treatment as established by Brehmer, and which in their essentials have not as yet been improved upon, are hyperaeration and increased nutrition. The first is attained by constant life in the open air, and the second by systematic feeding to the limit of the patient's capacity for assimilation.

Brehmer himself was an advocate of exercise in the open, while Detweiler introduced and has practised rest in a reclining position in connection with the "cure" at Falkenstein. At present the consensus of opinion is vastly in favor of the latter plan as effecting the best results, yet in this as in so many other medical doctrines extreme views are fraught with danger. One cannot resist the temptation to protest against a long continuance of a life of supine inactivity after the more urgent symptoms of the disease have subsided and the ravages of tissue waste have been compensated as shown by a return to, or nearly to, normal weight and temperature. That weight can be rapidly and enormously increased by a persistent adherence to a life of absolute rest and stuffing is certainly to be admitted but it has been demonstrated only too often that this increase above normal either in amount or rapidity is at the expense of the general well-being of the patient and is soon lost on return to the ordinary mode of living. It is well in this to be guided somewhat by analogy, and the fact is well known that stall-fatted cattle are far more prone to tuberculosis than are the grazing herds of underweight kine on the prairie.

On this point the recent work of Bardswell, Goodbody and Chapman, in the Brompton Hospital, is interesting and instructive, the conclusions which they reached are of sufficient importance to quote in full:

1. "That since very large diets gave worse results than those of more moderate amount, the indiscriminate stuffing of all tuberculosis patients should be replaced by systematic dieting. The diets as regards amounts and constitution should be determined in each case after due consideration has been given to the respective conditions as regards: (*a*) The activity and extent of disease; (*b*) amount below weight; (*c*) digestive capability; and (*d*) to some extent, personal dietetic likes and dislikes.

2. "That in view of the bad effect which overfeeding gave rise to in the normal individual, great care should be taken in the selection of a diet for patients who, as the result of treatment, have reached or passed their highest known weights. When this regain of weight is associated with arrested disease, the original diet found suitable for a person very considerably under weight and with active lesions, should be reconstructed more upon the lines of what would be suitable for the same person in perfect health.

"The observations were not sufficiently extended to allow of conclusions being drawn as to which diets gave the best results as regards the condition of the lungs; but subsequent sanatorium experience of two of us, with the advantage of being able to carefully observe the course of pulmonary lesions in patients upon weighed diets, leads us to think that the lungs do not improve any more rapidly upon forced feeding than upon generous diets. Futher, there is no doubt that anorexia, dyspeptic symptoms and vomiting are much more frequently met with when working with very large diets than when more moderate amounts of food are given."[1]

With regard to the kind and amount of exercise permissible and the class of patients to whom it is applicable I shall presently give the results of some interesting experiments and observations made at the Loomis Sanatorium Annex last fall. Of one thing we may be quite sure, that even in this matter of exercise and feeding there are no hard and fast rules which can be universally employed. In the sanatorium as in private practice, success in treatment in the highest sense is not to be attained by grouping and classifying patients and treating them accordingly. Each individual is a law unto himself and should demand attention and treatment on his own merits, irrespective of the class to which his condition might relegate him. In other words, the patient and not his disease is to be treated.

And this brings up the matter of medical supervision upon the efficiency of which depends the success or failure of the sanatorium. It is unfortunately true that in the past a certain amount of discredit has been cast upon these institutions through the occasional lapse from the proper ideals to those of the hotel proprietor. The commercial instincts of the inn-keeper are incompatible with the highest development of the sanatorium. The medical officer must have the helm and must never lose sight of the fact that he is, first of all, the physician; and that the relation which he bears to the management is that of the captain to the engine room. I believe that to the best interests of the sanatorium, it is essential that the medical officer should have had a more or less mature experience in private practice before undertaking institutional work. He has thus been taught to individualize his cases and to avoid the danger of treating them in groups and classes collectively.

In this connection I remember upon one occasion visiting a large military hospital for consumptive soldiers. At a certain hour, with soldierly precision, the bugle summoned several hundred ambulant consumptives into line. The surgeon-in-charge, an excellent man but with military training hopelessly ingrained upon his methods, then proceeded down the line, his assistants and orderlies reading from charts synopses of the last twenty-four hour records from which data the procedures for the day were prescribed and the men dismissed to quarters. Thus without elasticity or the least attempt at individualization the greatest possibilities of the sanatorium were lost. It represented better perhaps than anything else could have done—*treatment by averages*—a sort of medical "dead reckoning."

The medical staff of a sanatorium should be much more than the special inducement of a health resort hotel and in the few instances above mentioned where adverse criticism has been merited, it has, I think, been attributable to failure to recognize this fact. For efficient service the work in the sanatorium should be appropriately divided so that for every multiple of 30 patients there should be an additional medical assistant. Some authorities, I am aware, allow of a considerably greater number, but it is best to err on the right side in such matters and wherever possible to avoid the danger of falling into the thraldom of routine.

Of course, the narrower the limitations which govern the admission of patients the larger the number which can, with good judgment, be accorded to the service of one physician. But when a proportion of advanced cases are admitted, if any attempt is to be made toward individual clinical investigation, the staff must not be curtailed.

The laboratory of such an institution should be equipped not only for the ordinary clinical work but for medical research as well. Every sanatorium should aim to contribute its due share to the general fund of scientific knowledge on a subject so important to the welfare of the race as is tuberculosis. With such opportunities as are here offered for laboratory and clinical research it is surprising how little in the way of original investigation has been done in sanatoria; from this general statement, however, it is gratifying to be able to point to the splendid exception of Dr. Trudeau's Saranac Lake laboratory, which in a way is an outgrowth of the Adirondack Cottage Sanitarium and which has always been and always will be a credit to its founders.

While I admit that it might be too much to expect from the average sanatorium that it should in this respect emulate the example of the Saranac Lake institution, I still contend that there is much valuable labor of investigation well within the scope of every properly equipped institutional laboratory, and which when accomplished will add inestimably to our practical knowledge of the treatment of tuberculosis. I would suggest, for instance, further study into the problems of metabolism, a more systematic study of the sera and the formed elements of the blood, investiga-

tion into the shadowy unknowns of mixed infections, further research in dietetics and so on ad infinitum.

The question of nursing arises in every sanatorium where any but the earliest stages of the disease are admitted. I know of no class of invalids the care of whom makes more heavy demands upon the tact and discretion of the nurse than does the moderately advanced consumptive patient. The institutional nurse, therefore, should be chosen first with regard to her training which should be like the physician's—a special one upon a good foundation of general practice—and of no less importance, with regard to personal adaptability and resourcefulness. A well-qualified nurse who meets the requirements will do more to make the atmosphere of the infirmary cheerful, hopeful and unobjectionable, than any other one agency which it is possible to introduce.

We have now to consider what classes of phthisical patients are suitable for sanatorium treatment; what results may be hoped for and what duration of residence may be taken as the average minimum for each class. For the purpose of present convenience, tubercular invalids may be grouped under three heads: (*a*) those whose condition is hopeless; (*b*) those whose condition permits of an expectancy of an improvement or an arrest; and (*c*) those whose condition justifies a hope of cure.

Each of these groups has a distinct and peculiar claim upon institutional care and treatment as embodying the best practical therapeutics which for the time being are within the reach of the consumptive. The first on the ground of the weal of the public health no less than on humanitarian considerations. The second on the ground that extension of life, even when that life must be circumscribed by narrow limitations, is a worthy object and may have a value entirely disproportionate to what appears and the third on grounds too obvious to require argument.

An institution devoted to the care of hopeless cases, however, can scarcely even with the broadest interpretation of the term, be considered a sanatorium and accordingly need not here be discussed, but with the other two groups the average sanatorium has to do.

Until quite recently the true incipient type of the disease was comparatively seldom recognized, and as a consequence the average patient admitted to even the most exclusive sanatoria was one who to-day would be classed as advanced, yet the results as shown by the numbers discharged as "apparently cured" and "arrested" were remarkably gratifying. Now we know full well that the healed tuberculous lesions found in the autopsy chamber, in persons dying from other causes and which furnish us with such abundant evidence of nature's cure of the disease, are in the vast majority of cases, arrests in the early stages before softening has occurred. It therefore should require no argument to convince one that the earlier the case is placed under sanatorium treatment, which means after all merely placing the patient in the best possible condition for nature to effect its cure, the more certain is arrest secured and the shorter will be the duration of residence. It is therefore in the early stage that we should endeavor to obtain the cases for sanatorium treatment, but on the other hand, theoretically true as it may be that with sufficient vigilance advanced cases except in a few overwhelming infections, shall cease to occur, we have to face the fact that they *do* occur. It is indeed frequently the case that the insidious inroads of the disease have already produced advanced lesions before the patient is aware that he is ill and as fervently as it might be wished that it were otherwise we are obliged to accept these cases for sanatorium treatment. It is interesting and encouraging, therefore, to know what can be accomplished in these more advanced cases.

In a report of the treatment of 1,000 consumptives, at a sanatorium in Russian Finland, Gabrilowitch gives the following statistics: 122 were in the first stage, 720 in the second stage and 158 in the third stage, 72 per cent., therefore, were in an advanced stage on admission. On discharge there were 253 *cured*, 472 improved, 187 classed as "without result" and 88 died: 72½ per cent. were therefore cured or improved and 25.3 per cent. cured alone.[2]

That advanced cases, therefore, are often arrested and apparently cured when placed under suitable conditions is undeniably true and the sanatorium unquestionably has a scope of usefulness beyond the limitations of the incipient tuberculous patient. In admitting patients to the Adirondack Cottage Sanitarium, which excludes all but the earliest cases, Dr. Trudeau pursues an excellent plan for determining the suitability of cases: First is ascertained duration of disease, and if the patient has or has not steadily declined since then; second, the present status of the patient is noted with particular reference to amount of fever, sweats, cough and expectoration; third, chief importance is attached to rational symptoms rather than to physical signs. Those favorable for admission are (*a*) pleuritic cases, (*b*) cases with fair nutrition and slight impairment of health, (*c*) cases beginning with hemoptysis without constitutional impairment, (*d*) incipient cases.

Those unfavorable for admission are (*a*) cases which have steadily declined since onset; (*b*) cases showing a preponderance of constitutional impairment over comparatively slight physical signs; (*c*) those presenting complications especially laryngeal, glandular, intestinal, bladder, renal or joint affections; (*d*) all septic cases showing type of periodic hectic fever.[3]

Thompson Campbell, like Trudeau, would exclude patients who, although presenting slight objective findings have pronounced (evident) prostration of strength from the onset. He lays special stress upon the pulse frequency as a prognostic sign and unconditionally excludes all cases with albuminuria and pronounced tuberculosis of the larynx.[4]

In a sanatorium wtih sufficient infirmary accommodations, cases which might otherwise be excluded, may be admitted on a short trial with the hope, which is often realized, that the unfavorable type of the disease may be changed.

There is, to be sure, a certain type of laryngeal tuberculosis marked by more or less extensive ulceration with surrounding induration and edema of the mucosa, involving the arytenoids and often the epiglottis and usually accompanied with severe and painful laryngeal symptoms which are invariably associated with rapidly fatal cases, and unquestionably such patients are not to be materially benefited by sanatorium or any other treatment, and should therefore be excluded. But to class all laryngeal cases together as rendering patients unfit for the sanatorium is, I think, too sweeping a plan and does injustice to many whose condition is susceptible to great improvement or cure. Every laryngologist is familiar with that form of tuberculous ulceration occurring in the larynx usually on or near the posterior extremities of the vocal bands or in the interarytenoid fold, which under favoring circumstances (rest and suitable treatment) undergoes fibroid change and results in healing. Now the place of all others for such patients, it seems to me, is in the sanatorium where the facilities are at hand for giving them that constant medical supervision and favorable environment which are most needful and almost unattainable under ordinary conditions.

With a judicious selection of cases, therefore, laryngeal tuberculosis per se need not necessarily exclude a patient. If the aim of the sanatorium is merely to turn out the highest percentages of "cures" and "arrested" cases, however, I will admit that it is the *safer* plan to exclude *all* laryngeal complications.

It is well here to remark in parenthesis that by "constant medical supervision" I do not mean that persistent topical meddling with the larynx, which the inexperienced laryngologist is unfortunately too apt to practise. It requires but a little attentive observation to demonstrate how beautifully nature takes care of these "by-products" of tuberculosis as soon as general nutrition and vigor are brought to approach the normal.

The minimum duration of residence in the sanatorium and the results to be expected in a given case are questions which can only be answered tentatively or not at all. But we can on the other hand employ averages to some advantage, taking as standards the excellent and trustworthy statistics of Dr. Trudeau and Dr. Turban. From these we may gather that the minimum term of residence for the incipient and uncomplicated case should not be less than three months, while for the moderately advanced case with favorable symptoms a six months' residence may be considered as the mean minimum which will effect a satisfactory arrest or apparent cure. If these figures were more generally kept in mind there would be fewer instances of patients coming to the sanatorium with the comforting but misleading assurance from their family physicians that a few weeks' residence would be all that was required. When the term "cure" is employed in this connection we must distinguish as do the Germans between a "pathologic cure" and, as they put it, an "economic cure" ("wirtschaftliche Heilung"). To achieve the former it is obvious a much longer time is required. It appears, however, that when the latter is accomplished patients may safely be permitted to return to their homes and occupations—provided, of course, that their homes are clean and their occupations wholesome where, imbued as they are, with sanatorium methods relapse is comparatively infrequent and the pathologic cure finally effected.

The average duration of residence in the instance of patients discharged from the Loomis Sanatorium as "apparently cured" and "arrested" for the year ending October 31, 1902, was six and a half months in the case of those whose lesions were classed, on entrance, as "early" and "moderately advanced" the longest term of residence was 23.5 months, the shortest two months.

In a word the duration of residence and the results obtained will depend almost wholly upon the patient's condition on admission and his willing cooperation during the treatment. This latter factor is one which, while seldom difficult to secure if a little tact is exercised and the patient is even fairly intelligent, is of so great importance that without it the patient had better be at once discharged, both for his own good and for that of other patients in the institution.

As a matter of fact this difficulty is one which is rarely to be encountered in the sanatorium. No one can make even a brief sojourn at any of the great institutions without being profoundly impressed with three remarkable phenomena. First, the general air of good cheer and hopefulness which prevails. Second, the strikingly healthful and even robust appearance of the patients, and third, their evident capacity for large amounts of food. For those who have never visited an institution of this nature, there is a surprise and an education in store, and yet I have heard it remarked and with no little emphasis by some physicians that they could not bring themselves to advise their patients to go to a sanatorium because of the atmosphere of invalidism which they imagined could not but prevail there. This however is an old, and I am happy to say, declining fallacy born of experience in open health resorts and not in the closed sanatorium.

One has not to go far to discover the explanation for this cheerful attitude of mind on the part of these patients. There is a sort of communal sympathy and general interest in the fight which all are making which is perhaps the first cause. Then the gregarious instinct of the race finds the pleasantest possible expression under the circumstances in the cottage or pavilion life of these people all bent upon one object, namely, the recovery of health. Instead of inducing depression this stimulates courage and it is apparently recognized by the patients themselves that in this com-

munity of interests there is a moral strength which could not be found elsewhere. Whatever the cause, however, the fact remains that whether at Gerbersdorf, Falkenstein or Nordrach; at Davos or Arosa; at Saranac Lake, Asheville, and Silver City or at Liberty, the cheerful and healthful mental attitude which one finds prevailing within the precincts of the closed sanatorium, is in striking contrast to that which is often observed in the open resort.

Before proceeding to the final and more specific discussion of my subject it is well to say just a word in defense of sanatorium treatment as opposed to the argument in favor of carrying out sanatorium methods in the home of the patient. It has been argued that inasmuch as Brehmer's methods could be introduced into home treatment as in many cases has already been successfully done, it was therefore unnecessary to remove the patient from his family and friends and thus impose upon him a gratuitous sacrifice, by residence in a sanatorium; that the discipline of the institution while no doubt necessary there, was a feature which could not but be irksome and otherwise objectionable to the average American, imbued as he is with a jealous love of his personal freedom. Now it is my experience, and, I think, that of nearly all, who work in sanatoria, that with the intelligent invalid "no vigilance is fastidious, no skilled control vexatious." In the vast majority of cases we not only have the willing cooperation of the patient but when once he is made to understand the value and necessity of a systematic course of living, one obtains his enthusiastic support and he becomes at once a missionary in the field.

In the course of his address before the section for the Discussion of Sanatorium Treatments at the British Congress, 1901, Prof. Allbutt said: "The method was worked out in a sanatorium created for the purpose. It has been tested and perfected in sanatoriums, and if now it can be carried on outside of sanatoriums, which is not too readily to be admitted, this is so only by bringing the skill and conditions of the sanatorium into the home. I should look with little confidence on the home treatment of a phthisical patient by a physician unversed in the practice of a sanatorium, and by a patient who had not at least a month's training within its precincts. It is, as it were, to tell a boy at home to read his Caesar and his Xenophon, a little Euclid and algebra, to pat him on the head, bid him be good and industrious and promise to call in a week or ten days to see how he has got on."

It is unfortunately impossible to give every phthisical patient the benefit of residence in a sanatorium. We are, and for some time shall continue to be, for one reason or another, obliged to care for a considerable proportion of these cases at their own homes. But I still contend that wherever the choice is possible it should, in the majority of cases, be in favor of the sanatorium.

(To be Continued.)

## TUBERCULOSIS OF THE MIDDLE EAR, WITH THE REPORT OF A CASE.*

BY Z. L. LEONARD, M.D.,
OF NEW YORK.

As with other parts of the human body so the ear may be the seat of a manifestation of the tuberculous process. It may precede a general systemic infection which later develops in the lungs or in the parts remote from this location. Usually, however, it is secondary to an attack in other quarters which has progressed to an advanced stage. On account of its insidious, painless approach and because of the gravity of the disease elsewhere the trouble with the ear is overlooked, or if noticed, little attention is paid to it. It is more likely to excite the curiosity of the otologist and to be recognized by him as a sequence to his inquiring research.

As early as 1853 Wilde gave a description of the appearance of the drum-membrane and neighboring parts which antedated that of other writers on the subject. In 1865 Politzer more fully described the conditions by which tuberculosis of the ear might be recognized. This is all that was known with any degree of certainty, unless we except the writings of Buhl, who pointed out the fact that when pus was collected in an osseous cavity the walls facilitated absorption and tuberculosis supervened.

It was not until the discovery of the specific bacillus that a diagnosis could be made beyond the doubt of a denial of the existence of the disease in the ear. If it were not taken for granted that it was secondary to tubercular disease elsewhere it would be next to impossible to form a definite diagnosis from the appearance of the ear other than by excluding causes which lead to suppuration under ordinary circumstances. The discharge differs but slightly from that seen in a case of chronic purulent otitis media. It differs somewhat in this respect that it is less thick and more irritating as it flows over the healthy surface. But there are other signs which would draw the attention of the surgeon to the fact that he has to contend with a something which is out of the usual.

These symptoms should be almost, if not quite sufficient for him to arrive at a definite conclusion in the matter. It would be a comparatively easy task for solution when the disease was secondary to its inception in the lungs or joints, though rather more perplexing when the initial invasion was in the ear. An array of indications, like those about to be enumerated, would nearly cover all that can be known until the aid of the microscope comes to make assurance positive. For instance, the grayish spots in the membrana tympani before it has ruptured; the multiple perforations; the rapidity with which the bone yields to disintegration and the absence of pain. This combination is of so much importance that it would be within the bounds of reason and judgment to form a conclusion approximating defi-

* Read before the Harlem Medical Association, Mar. 4, 1903.

niteness without the certainty which the microscope gives.

In advanced cases a characteristic symptom would be the progressive destruction of tissue, even when other symptoms were absent or not sufficiently regarded by the surgeon. The discharge is not often of foul odor, although from the nature of such a case one would be inclined to expect it where the dissolution of bone moves forward in so rapid a ratio. It might be contended that many if not all of the symptoms discoverable to the naked eye are attributable to the existence of a cholesteatomatous mass, but Scheibe avers, "I have not been able to find Koch's bacillus in the cases of chronic purulent otitis with cholestatoma."

Tubercle has been found primarily in the mucous membrane of the middle ear and in the spongy tissue of the petrous portion of the temporal bone.

Lermoyez mentions that the latent tuberculosis of adenoid vegetations may be the origination of the disease in the ear, a fact which is not without influence when we reflect that these growths present themselves in close contact to the Eustachian canal and that the pharyngeal openings of these ducts are found to be widely dilated when tuberculous infection has invaded the aural structure. These patent orifices may have been the cause and not the result of disease in the ear, affording an easy egress to the bacilli which have remained quiescent in the pharynx, their exact locality not having been suspected. This is another confirmation that these products should always be removed by a competent hand, no matter what their size or the age of the patient.

The aspect of the perforation through the drum is diagnostic. As a rule they are two in number, but a few observers have detected more. Swain asserts, "multiple perforations are considered a sure presumptive sign of tuberculosis and my own experience would lead me to place as high a value upon this piece of evidence as I would upon the presence of a pyriform swelling of the arytenoid cartilages of the larynx, or upon that of a dull apex of the lungs." These openings soon run together to form one large circular perforation with thick, everted edges and a bluish-white edematous look. The deafness is noticed early and is progressive with loss of bone conduction and lowering of the upper tone limit when the labyrinth becomes involved.

It was Schwartze who, in 1878, first described the tuberculous nodules on the membrana tympani. In 1883 Esche demonstrated the presence of the tuberculous bacilli in the discharge from the ear. In mixed infection these bacilli, always few in number, gradually decrease as others increase. They may even disappear altogether as the disease in the ear becomes less severe for remissions and exacerbations are common. In this way cases have been observed extending over a long period of time the general health not having been materially affected. This, however, is not the rule, as it runs a fulminating course destroying every structure which would impede its rapid onward career.

The treatment must be similar to that which would be pursued in any case of purulent discharge from the ear, antiseptic, stimulating or by using astringents. But the treatment should by no means be localized to the ear, for these patients require active measures to elevate the general lowered condition and to put them in a position to oppose the further advancement of the affection. The otologist should never lose sight of the physician. Operative interference may be resorted to by opening up the mastoid cells if they should be invaded. Curetting away diseased tissue should be attempted with extreme caution, but is practicable in many cases, if precautions are taken not to be too thorough in the desire to remove portions lying over vessels or nerves likely to be harmed.

The case to be reported in connection with what has been said on this subject of tuberculosis of the ear is as follows:

*Case.*—A. M. C., aged twenty years, of American parentage, was first seen in the beginning of October, 1901. Parents were living and in good health. A brother and a sister had died of phthisis in early adult life. Members of the mother's family had also fallen victims to tuberculous disease. The patient was of a delicate appearance, fair of complexion and anemic. Until the previous winter, however, she had never had any severe or continued illness. At this latter date she had an attack of influenza, the recovery from which was exceedingly slow. The symptoms of this sickness expended their force in the nose and head with some pain in the ears but no discharge from them.

Whatever cough there was soon disappeared. The prominent and lasting symptom was that of lassitude. The patient's disposition had changed from that of cheerfulness to one of deep melancholy.

In the early summer of 1901, she was treated for malaria, or what was so designated, by the family physician. Later on she went to the country where there was a gain in strength and weight. In September, or two weeks before she came to me, on awakening one morning the pillow was seen to be soiled and the left ear was discharging a slightly offensive matter although there had been no previous premonitory signs that there was anything wrong with the ear. This flow was removed and the ear kept clean by the use of the syringe and warm water but no surgical advice was sought until her visit to me.

My examination disclosed the fact that there was an oblong opening in the posterior superior quadrant extending downward, however, beyond a central line. That part of the membrane which was still in situ was pale in color and the edges of the perforation were edematous and everted. The muco-purulent discharge was wiped away so that the tympanic cavity might be inspected as much as possible through the aperture. The mucous membrane was thick and jellified in ap-

pearance; the probe sinking into the softened tissue gave the impression that there was caries of the underlying bone. The part which was most to be noted for this charateristic was directly over the promontory and adjacent to it. The region of the attic did not appear to be implicated.

The absence of pain during any period of the disease was commented upon, especially when there had been such a destructive activity going on. The long handle of the malleus was eroded and a part had disappeared. There was no mastoid tenderness, nor had there been any, so far as the patient was aware.

In the vault of the pharynx there was a small growth of adenoid vegetations which were subsequently curetted away. The pharyngeal orifices of the Eustachian tubes were wide and patulous. The larynx appeared to be normal, there being no evidence of any enlargement of the arytenoids or of any congestion along the free border of the vocal cords. The respiratory murmur was clear in all parts of both lungs. There was no history of rheumatic or other pain in the joints at this examination, although this fact was elicited some weeks subsequently, but not, however, until after the right ear had begun to discharge.

Simultaneously with the exit of pus from the ear a loss of hearing was perceived which was steadily progressive in character. Both ears were involved in this deafness. Somewhat later, after the right membrane broke down there was a decided diminution in the upper tone limit lateralized more to the left. There was never any evidence that a cholesteatoma was the cause of the discharge. The case was regarded as one of ordinary otitis media purulenta and was treated in accordance with that view of it. Under treatment the amount of discharge lessened without ceasing totally, while the deafness increased and the subjective noises, hammering in the head, became almost intolerable.

In the last week of December, 1901, there was a discharge from the right ear, painless and gushing out during sleep to be first observed, as formerly with the left ear, on the pillow in the morning. On inspection a few hours later there were two perforations in the lower half of the drum membrane, a narrow strip of tissue separating the openings. From these there flowed a matter of the same consistency as that in the left ear. The probe passed into a jelly-like mass. The perforations were where there had been seen for some time before a clump of what were supposed to be petechial spots but which were in reality the tubercle nodules. A specimen of the exudation from each ear was now submitted for microscopic examination with the report that this investigation proved the existence of the tubercle bacilli in both. The perforations in the right membrane within a few days had coalesced into one large circular one with destruction of, at least, half of the membrane.

During the winter, despite all efforts to bring about a change for the better, the discharge remained practically the same. Curetting was performed several times, which seemed to be of benefit, but in March, 1902, a cough developed and it was found that the lungs were to become a part of the process of destruction.

In May she went away from the city and was not seen again until August. There was then a foul-smelling discharge from both ears which were blocked up with granulations and the deafness was almost complete, with vertiginous seizures.

There was consolidation of the right apex, tumefaction over the arytenoid cartilages, night sweats, emaciation and a constant hacking cough with expectoration. The patient was not seen again.

The inference drawn from this case is that the origin of the tuberculosis was in the ear, but the fact that both ears succumbed would perhaps give evidence to the view that it had begun in the vault of the pharynx extending upward. There is no doubt that the lungs were secondarily involved. Such cases are a witness to what should become a routine practice, to submit to the microscopist for diagnosis and verification the products of an unhealthy discharge not alone from the upper air passages but from the ears as well.

19 West One Hundred and Twentieth Street.

## THE PRESENT STATUS OF SOME OF THE PROBLEMS OF TUBERCULOSIS.*

BY JOHN L. HEFFRON, A.M., M.D.,
OF SYRACUSE, N. Y.

In March, 1903, twenty-one years will have passed since Koch gave to a waiting and expectant world the discovery of the tubercle bacillus. His treatise on the "Etiology of Tuberculosis" is a model of scientific writing. His observations were so accurate, his researches so far-reaching, his demonstrations so complete, and his deductions so logical that in the years that have passed nothing of any importance has been added to or taken from them by the great host of earnest colaborers throughout the world. This work alone will make his name immortal however Fate or Envy may tarnish the luster of his fame.

The impetus that was thus given to renewed study of tuberculosis cannot be exaggerated. The demonstration that the disease could be reproduced at will in susceptible animals practically made tuberculosis a disease that could be studied in the laboratory with the same degree of accuracy as are chemical and physiological processes, and it is to the laboratory investigators of tuberculosis, of whom Trudeau was the pioneer in this country, that we are indebted for all the advancement of our knowledge concerning the entire subject.

The demonstration that the tubercle bacillus is the essential etiological factor in producing tuberculosis and that it was always present in tubercu-

* The address of the retiring president, delivered before the Syracuse Academy of Medicine, Jan. 6, 1903.

lous discharges, was speedily followed by the convincing proof that its presence could be shown in the dust of infected houses, of churches, of the theaters, of public conveyances, from clothes soiled by expectorations and from the face and hands of the tuberculous. Experimentation and accurate clinical observation soon convinced all that the instances in which it could be conveyed from parent to child were so very few that direct heredity as a causative factor could be practically ignored. The tremendous import of this advance in accurate knowledge is not yet properly appreciated by the people or by physicians. The great white plague had cursed man so many centuries; it had become so familiar to every one everywhere; it had been seen to lay low whole families and to slay in successive generations so relentlessly, that a feeling of hopeless indifference had possessed the minds of men, and to this day much of that sentiment remains amongst the laity and amongst many who practice the healing art.

The other etiological factor, equally important, was recognized by the earliest of medical writers. By them, as by us, it was observed that unsanitary and unwholesome methods of life contributed directly to increase the number of victims of consumption, and of other diseases. They had known that anything which debilitated the individual made him more liable to succumb to disease. They knew the "soil" as well as we, and the most intelligent of them were as keen in advocating a return to natural modes of living as are we. I well remember the words of Professor Alonzo Clark in his lecture on the treatment of consumption. He said "Gentlemen, if I should become afflicted with consumption, I would go up to the Catskill mountains, buy a stage, and drive myself." Accurate clinical observations and laboratory research have conjointly demonstrated that to a congenial soil the universally distributed tubercle bacilli will find their way and will manifest their activities in one of their various modes of expression. This is absolute knowledge and is capable of demonstration to any one who has eyes to see. The problem for us is to see that this knowledge shall be the possession of every person whose mind is large enough to comprehend it, and to insist that sanitary laws must be enforced on those too ignorant to understand or too lazy or too wilful to yield intelligent or willing obedience.

Up to two years ago it was generally conceded that tuberculosis in man and in animals was one and the same disease, having the same essential cause and the same secondary causes, as crowding of cattle in insufficiently ventilated stables, etc.; that whatever differences in manifestations of the disease in man or animals were noted, and whatever variations in the form and characteristics of the bacilli were observed were due to their environment in their host, and that it was possible to produce tuberculosis in man by use of milk or meat which contained the living bacilli of bovine tuberculosis. At the London Congress of Tuberculosis in 1900 Koch, who originally taught this, gave as the result of his experience with tuberculosis in cattle and in man, some observations which went to discredit the probability that man was ever infected by tuberculosis from the consumption of milk or flesh from tubercular cattle. In the Berlin Congress in 1901 he reiterated this statement and analyzed all of the cases which had been brought to his attention designed to prove the contrary and in a way so masterly that at the end of his argument the cases cited were conclusively shown to be of no value as evidence. You remember the commotion this made, and the consternation it caused among those who had labored long and hard for the elimination of tuberculosis from dairy herds. To some of us it seemed to set back the hands of the dial of progress, and to make necessary another long struggle with the self-interest of the owners of dairy herds. Fortunately perhaps, his ideas were so bitterly opposed by such an array of men of eminent talent and of large influence in agricultural affairs, that the laws of the civilized world regulating the production of milk and the sale of meat were not seriously affected. Different nations and States have appointed commissions to investigate anew this deeply important problem, and a stimulus was given to individual laboratory investigators the like of which has not been seen in all these 20 years. Results are beginning to come in. Already several important papers have appeared, the most noteworthy of which in this country are those of de Schweinitz, who experimented with monkeys, and Ravenel whose conclusion of a most interesting paper, read to the Pathological Society of Philadelphia in April, 1902, is this, "The evidence at hand forces us to conclude that human and bovine tuberculosis are but slightly different manifestations of one and the same disease, and that they are intercommunicable. Bovine tuberculosis is, therefore, a menace to human health." While tuberculosis is a laboratory disease for animals, it is manifestly impossible to experiment on man, and therefore indirect evidence, and the evidence of experiments on man's nearest anatomical relations alone can be used. However, the evidence that other animals like swine and calves and lambs are frequently infected by milk from tubercular cows is overwhelming and not denied by Koch. In the debate in Koch's paper Nocard, in his remarks, said, "I may remind you of the fact established by your (English) chemist Thornton, and which proves the gravity of the danger. The general mortality in England for tuberculosis has diminished in 50 years by 45 per cent. Only one class of the population shows a contrary tendency, that is that of infants of tender years who die of abdominal tuberculosis. In this class the proportion has *increased* 27 per cent., as compared to a general diminution of 45 per cent. Nothing has been done to improve the sanitary condition of the milch cows and to prevent the sale of milk from those with tuberculous udders." It would seem to me, therefore, that the burden of proof is on Koch's side, and that until he can prove to the

perfect satisfaction of men as skilled in laboratory work and as keen in observation as he is himself that infants are *never* infected by the use of milk from tuberculous cow his case is not won, and that we will be unwise to relax in the least our most stringent rules concerning the sale of the milk and meat from cattle infected with tuberculosis. Under such conditions we can wait with patience until this problem of the intercommunicability of human and bovine tuberculosis is definitely settled.

The *diagnosis* of tuberculous disease in its very beginning is often a matter of great difficulty. After the process has advanced to the production of gross lesions, with their attendant symptoms any one can recognize it. In the meantime the golden opportunity for curative treatment has been lost. In my experience it is not the rule to see a case of tuberculosis at a period so early that it can be rightly termed "incipient." This is due to two reasons: first, to the negligence of the patient himself, secondly, to the carelessness or superficial examination given by the doctor to whom the patient first applies for medical advice for what he considers some trifling departure from health. If we could constantly hold in mind that practically everyone is daily exposed to the tubercular infection and hold under suspicion everyone who applies for counsel who does not present data for a definite diagnosis or who does not show a rapid amelioration of his symptoms, we would not see in the reports from sanatoria the statement that 60 per cent. of applicants sent as suitable for treatment are rejected year after year because their disease had advanced so far as not to give promise of cure. As a matter of fact nature is kinder to us than we are to ourselves or to each other. The reports from the large hospitals in which great numbers of postmortem examinations are made show tuberculous lesions healed or active in at least 50 per cent. of all cases examined macroscopically. Naegeli has reported a successive series of 500 autopsies in a general hospital in which, by the aid of the microscope, he demonstrated the presence of tubercular lesions in 99.9 per cent. of the cases. Welch has said that if such lesions be sought with diligence in all the tissues the proportion will not be found to have been exaggerated by Naegeli. With the universality of the infective principle and the known exposure of city dwellers to it, I do not see how we can escape such a conclusion. The attitude of the physician should be one of expectancy to find the evidence of tuberculosis and he should not rest satisfied in any case under the least suspicion until he has demonstrated beyond the shadow of a peradventure that his patient has or has not a tubercular infection. The cultivated diagnostician will detect the slightest variation on comparative examination of the chest by all the methods known to art. Allbutt has said that he who has not a musical ear should not practice percussion and auscultation in cases in which an early diagnosis is of such great importance. But long before any change has taken place that the most expert in physical diagnosis can possibly detect the invasion has begun in the lungs, and if we await the evidence to be elicited by the usual methods, and particularly if we wait until the sputum reveals the presence of tuberculous bacillus which always means that the process of ulceration has already begun, we have lost most precious time. Again, the invasion is not always by the lungs but frequently enough in the lymphatic glands of the neck or of the mesentery or in other organs of the body and in such cases an early diagnosis by gross methods is once more impossible. Persistent malaise with loss of appetite and strength and later with a daily rise of temperature of a fraction of one degree with pulse of lowered tension and increased frequency and the onset of a slight cough, combine to make the alert physician suspicious of tuberculosis where no physical signs can be detected. I know of no single observation of more value both in diagnosis and prognosis than accurate thermometry. To make such observations of value one must attend personally to every detail. A thermometer of known accuracy must be used under unvariable conditions by a person most interested to record the exact truth. In my experience I have found I can trust the patient to make such observations as I do not make myself with more safety than I can any one to whom his care is entrusted. Not infrequently before the temperature is elevated even a single degree, the pulse will be changed in frequency and character, especially in persons of nervous temperament. With a careful investigation of the history of each case presenting and attention to the significance of the symptoms just discussed, an early diagnosis can frequently be made before any physical signs manifest themselves and before a single tubercle bacillus can be discovered in an examination of the sputum. If that prove impossible modern science has contributed other methods of diagnosis that will absolutely settle the truth. In 1900 Koch once more set the whole world ablaze by another astounding announcement. This time his message fell on the ears, not only of physicians, but of those in the throes of the dread white scourge. Such an assemblage of notable men eager to learn the truth of his announcement of the discovery of tuberculin and its virtues as a specific for the cure of tuberculosis, and such a mob of sick men and women eager to be cured never was seen in any city as gathered in Berlin immediately after the publication of this news. The announcement of his discovery of the tubercle bacillus was done in the most scientific and open manner. The cure, tuberculin, was held as a secret which he did not give to the medical world until the investigation of others in the same field of work practically disclosed it. Its reputation as a specific in the cure of tuberculosis was short lived. However, much good came of it, for it was speedily proven to be the most delicate test by which to prove the presence of tuberculosis in suspicious cases in which a diagnosis by no other means could be definitely asserted. Its use for

this purpose has steadily increased and to-day the verdict of those most expert in the diagnosis of tuberculosis is that it is absolutely reliable and that if properly used, it is never injurious. Koch has modified his original method of producing tuberculin twice ,and now uses what he terms "tuberculin emulsion." This is made by grinding the dried living bacilli for weeks in a mill, then centrifugating the powder suspended in water to throw down any clumps and unground bacilli, then by keeping this recovered product in 50-per-cent. glycerin solution at least two weeks before it is put on the market, which process he claims kills any remaining living bacilli. In the Saranac Laboratory it was proven that his second modification, "Tuberculin Reste," or "T.R.," was capable of producing fatal tuberculosis in guinea pigs, showing that living bacilli were still present in the product sold. A Swiss investigator, Fritz Thellung, has recently published an account of his experiments showing that the specimen of this latest tuberculin emulsion is also not free from living T.B., and caused fatal tuberculosis in guinea pigs. It is evident that care must be taken to exclude the use both of the T.R. and the T.E. tuberculin, and to use for diagnostic purposes only the original tuberculin which is made perfectly sterile by boiling for 48 hours. Concerning the use of this tuberculin for diagnostic purposes I cannot do better than to quote Koch's own words taken from his address at the London Congress in 1901.

"For this (diagnostic) purpose I use the following method. In the first place the patient's temperature is observed for at least one day, or better two, in order to ascertain whether the temperature is below 37° F. Patients whose temperature is above 37° F. are unsuited for the diagnostic application of tuberculin, and ought not under any circumstances to be subjected to the tuberculin test. If the patient is found suitable he receives an injection of tuberculin under the skin of the back in the forenoon; with weak patients one begins with one-tenth milligram; with stronger ones, whose tubercular alterations are probably very slight one may begin with one milligram. If there is no rise of temperature at all, one gives a dose double as large as the first, not on the next day, but on the day after the next; but if there is a slight rise of temperature, only a quarter of one degree, for instance, the dose is not raised, but repeated as soon as the temperature has gone down to the normal level. It very often happens that, though the same dose has been given, the second reaction is stronger than the first. This is quite specially characteristic of the effect of tuberculin, and may be regarded as a quite infallible sign of the presence of tuberculosis. But if the first small dose produce no reaction one gives five and even ten milligrams. For certainty's sake I am accustomed to give this latter dose twice, and only when no reaction occurs do I feel justified in assuming that the case is not one of fresh or progressive tuberculosis demanding specific treatment." Without question this is the most delicate diagnostic method which we can employ to-day. Koch reports its use in 3,000 cases. Evidence of its usefulness has recently been published in a careful paper by Dr. J. D. Madison, who reports 40 per cent. of reactions in 400 women in the Danvers Insane Hospital in Mass., to whom it was given experimentally.

The use of tuberculin for diagnosis is not without its opponents, some of whom have claimed to observe injurious effects. Dr. Trudeau assures me that in all the cases in which he has used it there has never been any but temporary discomfort from the reaction. He is careful never to exceed a dose of 10 milligrams. In discussing the possible dangers from its use Dr. Madison says, "In considering the dangers of tuberculin, it is well to remember that we continue to use chloroform and ether for diagnostic purposes, notwithstanding the fact that many deaths are known to be caused by them; and surely there are few diseases in which an early diagnosis is more important than in tuberculosis." But we have another method of diagnosis, not so delicate and not so easily applied, and, in fact, useful only in the hands of a skilled and trained observer, in the X-ray. Dr. Baldwin of Saranac tells me that with our Fellow Dr. Clifford Mercer they made use of the fluoroscope to a considerable extent during the past two winters and that they found it of value in about 5 per cent. of the cases examined. It may well precede the use of tuberculin and diminish to some extent the number of cases in which tuberculin may prove a necessary test. He who has a constantly expectant attitude of mind, power of accurate observation, trained skill in physical diagnosis and can avail himself of the services of a Weigel or a Williams with his X-ray photographic plates or his fluoroscope, and who, when necessary, can follow the accurate directions of Koch in the use of tuberculin and can accurately estimate the reaction produced, cannot fail to detect tuberculosis in its very earliest manifestations in such cases as present themselves for diagnosis.

The present status of the *prognosis* in tuberculosis shows a marked change from that of twenty years ago. Throughout the world the number of deaths from tuberculosis is gradually decreasing, even with our present insufficient means for caring for the tubercular poor. England heads the list and shows a decrease of 45 per cent. in deaths from tubercular diseases in the last fifty years. In our own State there has been a gradual decline but in no such proportion as is shown by England, though for the past year a death rate of but 2.7 per cent. per 1,000 is shown in Greater New York. That the death rate is still appalling the following figures taken from a recent publication of the commission for the establishment of sanatoria in New Hampshire are proof. An analysis of all the reported cases from 1884 to 1901 showed that from the age of twenty to thirty years the deaths from tuberculosis were 40.72 per cent. of all deaths in that decade of life; from thirty to forty years they were 31.38

per cent.; from forty to fifty years, they were 19.53 per cent. But the reports from modern sanatoria for the treatment of tuberculosis show conclusively that the prognosis is the more favorable in exact proportion to the period at which the cases come under treatment. The earlier the case comes under treatment the better the prognosis. Dr. Trudeau reports that during the years 1897, 1898 and 1899 72 per cent. of incipient cases were discharged apparently cured, while only 17.8 per cent. of advanced cases recovered. Dr. Bowditch, of Boston, reports that, of purely incipient cases, in 79 per cent. the disease was "arrested," while of a total of 201 cases, 42.23 per cent. showed arrest of the disease process. Dr. Weicker of Goerbersdorf stated at the Berlin Congress that 97 per cent. of the cases received in the "initial" stage and discharged as cured in 1896, 1897 and 1898 were at work on Jan. 1, 1899, while on the same date, of those who were classified as "advanced phthisis with destructive process" and were discharged in the same year 77 per cent. were dead. Such figures might be multiplied but these suffice. They all teach the same gravely important lesson, that the prognosis is good or bad according as the patients come under observation and scientific treatment early or late. But there are some other words to be said on prognosis. We have all of us seen cases that have advanced to cavitation that have recovered and have remained well for long periods. I could give several such examples from my own notes of men who are living and working and in whom I demonstrated the existence of cavities of considerable size, 5, 10 or 15 years ago. On the other hand we have all seen cases which we have watched from the first faintest signs of disease or who have had the best opportunities to recover who have gone from bad to worse and have speedily died in spite of all efforts in behalf of their recovery. In a person of good parentage from a physiological point of view, who has inherited a good degree of resistance, there is hardly any stage of tuberculosis in which recovery may not be possible. Of all diseases tuberculosis is the one which is fullest of surprises. The *prognosis* of tuberculosis is thus seen to be generally better than it was 20 years ago, and is the better the earlier the disease is recognized, and put under the treatment which to-day is recognized as the best.

One of the most interesting and important problems is the question of *immunity*. In the light of such reports from the post-mortem chamber as those of Naegeli it is questionable if there be any such thing as natural immunity. Of course those cases were those of city dwellers of the lower classes, but if the perfect specimen of manhood produced under the most favorable circumstances in the country were subjected to similar conditions is there good reason to think that he would go unscathed? The natural tendency to recovery from disease is recognized by all. It is the "vis medicatrix naturæ"—but this is not immunity. The gift of bodily perfection and the wisdom to maintain it are more to be desired than any immunity which science can confer. But few of us have this gift, and more of us fail to keep intact such inheritance as we have, and so the impetus to investigators to find that which shall give the human race immunity from tuberculosis which shall equal that conferred by vaccination against smallpox is not wanting. An immense amount of work has been done along this line and never more than at this moment. The attitude of laboratory workers is that of hopeful expectancy, almost faith, that that which has eluded them so long will shortly be discovered. In 1893 Trudeau published a series of cases which went to show that vaccination of susceptible animals with T.B. attenuated by repeated tube cultures for a number of years protected them from developing tuberculosis when inoculated with T.B. known to be virulent and which proved fatal to unprotected control animals. These guinea pigs died after two years and were then found to be tuberculous, but they had lived two years longer than the controls, and two years of a guinea pig's life would correspond to two decades of the life of a man. In 1894 de Schweinitz reported some experiments giving similar results. Recently renewed interest in the question of immunity has been awakened. In 1901 von Behring conducted a series of experiments on cattle, repeating the work of Trudeau on rabbits and guinea pigs. By vaccination of cattle with human T.B. grown in tubes for a period of six years he has made them apparently immune to virulent bovine T.B., at least they have survived the inoculation, while the control animals succumbed with acute miliary tuberculosis. Pearson and Gilliland have repeated and confirmed von Behring's results on cattle. After a sufficient time shall have elapsed to determine whether this apparent immunity is complete and that the immunizing serum is innocuous and after it shall have proven successful and harmless to animals more nearly allied to man than are cattle, it can then be safely tried on man himself. When the immunizing serum shall have been produced it will be available for therapeutic purposes. Until that glad day shall come we must proceed on principles already laid down, which have proven so successful in the hands of those who use them.

In the *treatment* of tuberculosis there are certain general principles which cannot be too often repeated. The physician himself must first become thoroughly permeated with the truth that tuberculosis is a curable disease, curable more readily the earlier it is detected, but curable, under the most advantageous circumstances in a considerable percentage of cases, in every stage of its expression. This idea has not yet possessed the profession, and in my opinion the present death rate of tuberculosis is greater than it should be from this very fact. I am conscious of no greater responsibility than that which is assumed by a physician with a live conscience who takes upon himself the care of a tubercular patient. When one is inclined to be pessimistic and to feel

that whatever his efforts the battle will inevitably be against him in the end, let him think of Trudeau and his great achievements and of a host of other noble men who have been his patients and his pupils, and of a long list of other men in our own profession who have themselves been tuberculous and to whose untiring and intelligent efforts we owe the present favorable outlook for those once without hope. At a dinner at Denver last summer at which were seated those whose names are familiar to all phthisiotherapeutists I asked my neighbor how many of the physicians at table had come to Denver because of their lungs. After a rapid survey of the company he answered "All but two—and they came because their wives had tuberculosis." Because of the records from modern treatment and because of my personal knowledge that a large number of our own profession who have contributed grandly to the progress of the world of science, have been cured, I wish to emphasize the fact that the first essential for the successful treatment of tuberculosis is an enthusiastic belief in its curability. When you are yourself imbued with this spirit you are prepared to communicate it to your patient. When the diagnosis is accurately made the next duty is to take your patient fully into your confidence. He is to be encouraged to plan a campaign, not a battle, against an enemy who is completely revealed and whose maneuvers can be accurately determined day by day. He is to share your enthusiasm, and he himself is to be on duty to detect each evidence of advance or of recedence. I have never seen anything but good from such a method of procedure. My patients are all taught the nature of their disease, its natural history, all the essential points in the management of it, and they have proven my most reliable observers of temperature and of all data that do not require the special fitness of an educated medical mind. Intelligent obedience to commands that are seen to be based on correct principles is willingly given, while the perfunctory following of orders simply because they emanate from a selected physician lacks spontaneity and soon grow irksome. This feeling of enthusiastic hopefulness and of implicit faith in one's medical adviser has often won the day when all things looked discouraging indeed. It seems to me that this mental attitude on the part of both physician and patient, which is so essential, has become possible only as the result of accumulating evidence, increasing year by year from laboratory investigation and from clinical observation during the past two decades. If it be asked "Is there a cure for consumption?" the answer cannot be "yes" or "no." The verdict of this moment in the twentieth century is that there is no "specific cure" for this disease, in spite of the assertion of many who have access to medical journals and even to the privileges of a Congress for Tuberculosis. If one reads the Transactions of the Congress for Tuberculosis which met in London in 1900, and which is only recently accessible in full in this country, he must be struck by the fact that while the most eminent men in the field of medical science took great parts in this notable gathering, there was no attempt to rule out those who came with a pet fad. Although laboratory investigators have proven the fallacy of every specific treatment that has yet been proposed, by accurate and convincing experiments on tuberculous animals, you will find here papers advocating as specifics "izal," "igazal," "formaldehyde," "phosphate of lime," "natural serum," so-called "antitoxic serum," "urea," the "Crotte method" by which formaldehyde is supposed to be shot through the lungs by the aid of an electric spark, and so on. If tuberculosis were not a laboratory disease and if all proposed remedies had first to be tried on man instead of on animals, and if evidence depended only on clinical observation, we would certainly be at sea. In a disease essentially chronic, which under favorable circumstances tends to recovery, clinical evidence is least valuable. In a recent address by Trudeau on "The History and Work of the Saranac Laboratory for the Study of Tuberculosis," read before the Laennec Society at Johns Hopkins Hospital, he said, "We soon learned that the tubercle bacillus bore 'cheerfully' a degree of medication which proved fatal to its host," and "While they (proposed specific germicides) had no influence on the tuberculous process, they often tended to shorten the lives of the treated animals," and further on, "Neither our serums nor any of those proposed by other experimenters were found capable of saving a tuberculous guinea pig from a fatal dose of tuberculin." In the light of such evidence only the self-deceived or the deceiving could possibly say that a "specific cure" had been found for tuberculosis.

This negative answer to our question disposes of all attempts at treatment directed against the invading host, the tubercle bacilli, but a powerful and affirmative answer comes when we gather the evidence concerning the effects of treatment directed to the host invaded, the infected man. All of the greatly improved results which modern medicine is recording are due to our successful efforts, as Otis puts it, "to develop and strengthen the resisting power of the consumptive until his pulmonary tissue presents no longer a favorable soil for the infecting germ." The essentials of this treatment seem simple—rest, generous feeding, and life in the open air. Do you remember that significant experiment of Trudeau's away back in eighty-six, when he inoculated a lot of rabbits with tuberculosis and consigned one-half of the number to the free life of an island in an Adirondack lake, and the others to a life under conditions as unhygienic as he could devise? The latter were all dead in three months. The lot set free on the island all "recovered or developed only a localized disease."

By rest is meant not only rest of body but rest of mind as well, so that in considering the separation of a patient from his home, his dependency on home friends and the conditions under which he leaves them must be carefully weighed. Homesickness has thwarted many well laid plans, and

worry about the support of his family has destroyed the beneficial effects of the open air treatment in the case of more than one infected breadwinner.

The details of diet need not be discussed. It would be an experience of great value to any physician to dine at one of the recognized sanitoria. The abundance and variety of nutritious and well-cooked food served to patients would illustrate the extent to which hyperalimentation is successfully carried better than any words could do.

The success of the open air treatment has been so marked that many explanations have been proposed to account for it other than the simple use of ordinarily pure atmospheric air. It will be remembered that, when the Adirondack region was beginning to be exploited as a desirable region for the tubercular, Dr. Loomis proposed an explanation for the superior advantages of the forests, asserting that the evergreen trees had the power of converting the oxygen of the air into ozone. I remember to have been much impressed by this explanation, but the relentless experimenter soon disposed of this theory, and ozone was found of no more value than the ordinary admixture of oxygen in the air we breathe. The temperature of the air was then investigated. It was shown that the growth of the tubercule bacillus was inhibited by a temperature above a certain point. As a practical result it was proposed to treat the tuberculous with superheated air. Many interesting devices were made by which this idea could be carried out. Again it was proven that the tubercule bacillus could not grow luxuriantly if the temperature was kept below a certain point. This resulted in the explanation that the great good of the open air was due to bathing the affected area in air at a temperature below that at which it developed readily. The physiologists had always taught that the temperature of the air below the trachea was practically unchangeable by external conditions of temperature, and that the tissues of the lungs did not differ from other tissues in the body in maintaining an unvariable temperature under usual conditions. The laboratory investigator soon settled this question by demonstrating that the temperature of the lungs was not changed by the change in the temperature of the inspired air, and so the conception that the *bacilli inside of tubercles* were chilled by the low temperature of inspired air and so inhibited, or were discouraged by a temperature higher than 100° F. had to be abandoned, though it has died a slow death. In fact man's ability to stand high and low external temperatures had long been considered to be due to such a physiological mechanism that neither high nor low temperatures under normal conditions of the individual could materially change the normal body temperature. The repeated observations that patients did better in winter than in summer in many of the sanatoria was taken to indicate an advantage due to the temperature, but such an advantage is explained by the greater activity of the metabolic processes, calling for a greater consumption of food in winter than in summer, and to the increase of the sense of well-being brought about by an improvement in digestive ability, which brings with it also an increase of reserve power and of resistance. That there is a definite and measurable change in atmospheric conditions from the level of the sea to the tops of lofty mountain peaks is certain, and for ages physicians have made use of this knowledge. That this can be made use of in various cases to the great advantage of patients is unquestionable. The accumulated evidence of the relative curative properties of the pure air of the sea level or of elevated regions is of great significance and needs to be carefully studied by the ærotherapeutist. It has hitherto been taught that the individual who developes tuberculosis is more rapidly cured in a climate marked by conditions different from those under which he developed the disease. I have seen many examples which served to illustrate this fact. The resident of a region low in elevation and heavily charged with moisture has made apparently more rapid advancement in moderately high regions where the air is dry. I have seen several instances of the reverse of this, where individuals who had become tuberculous in the high and comparatively dry climates of the western tablelands have speedily recovered at such a place as Lakewood. But recently the experience of sanatoria at different localities has seemed to indicate that this selection is not of such importance as it has been considered. I am not yet prepared to give adherence to this dictum, but I am convinced that, under favorable circumstances, a tuberculous patient *can* recover in any kind of an atmosphere, provided it is mechanically and bacteriologically clean, and is enjoyed continuously day and night, and I am inclined to think Dettweiler is right in asserting that it is important that a man be cured in the climate in which he expects to carry on his business. This last statement, and its confirmation in the results obtained in local sanatoria for the poor, puts a new phase on the subject. It means that hope can be given to those to whom it is impossible to say that a prolonged residence at far distant places is necessary because for so many such a method of treatment is beyond the limits of the possible. Without attempting a complete discussion of this subject, for which the limits of this paper would be insufficient, let us take up the last of the problems it is proposed to review to-night: *What should we do with the tuberculous poor?* The condition of this class of society is pitiable beyond expression. In the family of the laboring man at least the position of the husband and wife is equal in importance. If the man is laid low, income ceases, if the woman is the victim of disease, the wages are not sufficient to meet the uncommon expenses. The state and the municipality has a duty to them which it has been slow to recognize but which is imperative. The general hospital of cities and towns is shut to the tuberculous poor,

and, on sanitary grounds, this is right. But it is not right that no provision should be made for this class of cases save what is furnished by the hospitals of county poor houses. If these are used they are found to be but places in which the disease may run its course unchecked and without any attempt to make use of the modern treatment of tuberculosis. The most accurate reports from sanatoria for the treatment of tuberculosis show that at least 75 per cent. of the incipient cases can be arrested, and that a larger number than that can be so far restored to health as to return to avocations that will permit of self support. This is an enormous advantage economically to the State. If we compare with this the results obtained in our state hospitals for the treatment of the insane we will find that the outlook for recovery for the cases of incipient tuberculosis is greater than that for the insane.

Through the kindness of Dr. Hutchings of the St. Lawrence State Hospital for the Insane I have been furnished with these statistics:

"RECOVERIES IN THE ST. LAWRENCE STATE HOSPITAL.

| Year Ending. | Original Commitments. | Recoveries. | Percentage. |
|---|---|---|---|
| Sept. 30, '02..... | 264 | 89 | .337 |
| " " '01..... | 285 | 87 | .305 |
| " " '00..... | 268 | 81 | .302 |
| " " '99..... | 300 | 93 | .310 |
| " " '98..... | 281 | 81 | .288 |

"In addition to the above there were discharged in a greatly improved condition, but not actually recovered, the following: 1902, 25; 1901, 29; 1900, 45; 1899, 35; 1898, 37.

"The cases considered as improved were in the great majority of cases able to resume their usual employment but still entertained some peculiarities which would distinguish them from so-called recoveries in whom no mental symptoms whatever remained." This creditable showing for one of our large state hospitals for the treatment of the insane has been accomplished by the State of New York at an outlay for the entire state of no inconsiderable sum as these figures kindly furnished me from the Comptroller's office will indicate: "The amount expended by the state for building, equipping and furnishing the state hospitals for the insane, to September 30, 1902, is $21,605,065.29. For building, etc., Craig Colony for Epileptics, the only state institution of the kind, the amount expended for the same period is $783,776.85. The total number of patients in the state hospitals on September 30 last was 23,265, and in the Craig Colony for Epileptics, 826. The amount of payments by the state, for the fiscal year ending September 30, 1902, for the maintenance of the state hospitals for the insane was $3,777,529.45, and for the Craig Colony for Epileptics, $128,000."

We are proud to be residents of a State which cares for two classes of unfortunates so bountifully and so successfully. I am not in possession of official statements from Craig Colony, but the general impression is that such an institution cannot hope to be curative but only a hospital for detention. That the great good done by such institutions could be more than equaled by the scientific care of the tuberculous poor the following communication recently received from Dr. Vincent Y. Bowditch is convincing: "Most certainly I believe that every dollar expended by Massachusetts for the State Sanatorium at Rutland has been more than repaid, not only by the good done to the individual sufferers from tuberculosis, so many of whom since their stay at Rutland have become wage-earners again and a large percentage of whom have remained to all intents and purposes perfectly well since, but on account of the educational effect upon the whole community in showing what the simple and essential laws of hygiene will do for the prevention and cure of disease. If we can make people wage-earners again, how much more valuable such institutions are than those which are merely resting-places, however essential they may be, for the poor insane and epileptics who are of little or any use to themselves or the community at large. I cannot speak too strongly to express my feeling in favor of the establishment both of sanatoria for the hopeful cases by the State, and also of hospitals in cities and counties for the hopelessly sick, to be under the supervision of the municipal and county authorities." The State of New York has done something. Two years ago, as the result of a movement which this writer had the honor of first proposing in the Medical Society of the State of New York in a paper read in 1896 and which was most ably carried to an issue in 1900 by a symposium on "State Care of the Tuberculous Poor" planned and executed by one of our ex-presidents, Dr. Henry L. Elsner, the State of New York made an appropriation of $100,000 for the establishment of a State Hospital for the treatment of incipient cases of tuberculosis among the tuberculous poor. It was my privilege to observe last week that the cellar had been commenced at the selected site, Ray Brook, four miles from Saranac. Of course this hospital when completed will be wholly inadequate to care for more than a very small fraction of the cases suitable for admission within its walls. But it will mark the beginning of better things to come. If it shall be free from political control and be given to the most scientific treatment of selected cases it will not be long before its records will prove inspirational to our legislators, and from this will doubtless grow a more intelligent policy in the care of all curable cases of tuberculosis. But accessory to State hospitals there must be in every county and near every city of the first and second classes in our State, local hospitals for the tuberculous which shall receive all cases and in which cases can be watched sufficiently long to determine whether they are suitable for treatment in State institutions or whether they should remain permanently in local institutions. Such hospitals must be so controlled as not to be made simply hospitals of refuge to which no self-respecting tuberculous patient would be willing to be consigned; they

must be managed with all the attention to details for curative institutions that modern skill can devise; they must have a corps of medical officers that shall command the respect of the community at large, and they must be independent of the county poor house. To the end that our own city shall soon have a hospital that shall meet these demands, the influence of this organization is necessary. But while we wait hopefully and expectantly for the consummation of this plan, we need not be inactive. The example of the Greater City of New York which has greatly ameliorated the condition of the city's tuberculous subjects and has already effected a marked diminution in the death rate for consumption is before us and is worthy of imitation. The plan conceived and executed by Dr. Hermann Biggs and his coadjutors has proven so comprehensive and so successful that it has had the favorable commendation of the great Koch himself, and, until more perfect measures can be carried out, it should receive our earnest study. This Academy should support our local Board of Health which has undertaken to carry out most commendable provisions, particularly those which aim at the education of the people in a correct knowledge of what tuberculosis is and how it can best be avoided and prevented. In the campaign of education the local authorities might well invoke the cooperation of all sick benefit societies, industrial insurance companies and all large manufacturing con-

At the risk of imposing upon your patience I have gone over superficially some of the most important of the problems of tuberculosis. No attempt has been made to treat any topic exhaustively, and only those most needing emphasis have been touched upon. It is only by repetition of such well-known facts as have been here gathered together that we can awake in the public and in the profession a proper appreciation of the importance of a subject that has become so familiar to us that it has almost "bred contempt." This awakened interest would be manifested most effectively by the establishment in every city of a Society for the Prevention of Tuberculosis.

## MEDICAL PROGRESS.

### OBSTETRICS AND GYNECOLOGY.

**The Treatment of Gonorrhea of the Uterus.**—This depends on the situation and chronicity of the disease; according to the judgment of GEORGE W. NEWTON (Am. Jour. of Obstet., May, 1903), it is difficult to destroy the gonococci in the uterus as the ducts of the Nabothian glands of the cervix furnish a most excellent hiding place and that it is difficult to get at them with either drugs or the curette. They may also have penetrated the muscular structures so that it is impossible to reach with the curette. When the disease is limited to the cervical canal the discharge should be removed with the author's brush. This brush will remove the tenacious discharge in a second's time most perfectly. Then to the membrane which lines the cervix, a mixture containing 40 per cent. of carbolic acid and 60 per cent. of iodine should be applied with prepared cotton on an applicator, care being taken that none of the mixture goes beyond the internal os. If there is much erosion about the external os after making the application of iodine and carbolic, a tampon wrung out in one per cent. creoline should be inserted into the vagina, and the patient should use daily douches of creoline. The applications to the cervix should be made twice a week. After the disease has gone by the internal os the treatment varies with the chronicity of the disease. If the gonorrheal process is subacute put the patient to bed, prepare her as carefully as if she were to have a hysterectomy performed, dilate the uterus carefully but thoroughly, then flush the uterus with two quarts of sterilized water; follow this with a few ounces of a one-per-cent solution of protargol, then lightly pack into the uterus gauze saturated with two per cent. protargol. Allow this gauze to remain in the uterus for twenty-four hours, at the end of which time it should be removed. If the disease is chronic exactly the same procedures should be carried out except that the uterus is curetted with a sharp curette. It cannot be stated at the present the exact percentage of the cases of gonorrhea that can be cured by these methods of treatment. Six cases treated by the author after this fashion have been apparently cured as the secretions from the vagina and uterus failed to show the presence of the gonococcus. Six months after they had been operated upon, the symptoms had also disappeared.

**Treatment of Cancer of the Cervix by the X-ray.**—Of all the conditions which the gynecological surgeon is called upon to treat or operate upon, there is none quite so terrible as, or more painful in all its manifestations, than cancer of the uterus and its appendages; furthermore there is no condition where the major proportion of the cases finds us so helpless or powerless to bring about a radical cure. THOMAS P. SCULLY (Ann. of Gyn. and Ped., May, 1903) says that during the past year several men have been investigating the use of the X-ray in such places within the body as the rectum and vagina; and, while each was still unaware of the other's endeavors, all have arrived at practically the same conclusion as to the manner in which the X-rays could be used successfully. E. W. Caldwell of New York City has described a specially constructed tube for this purpose. It is a unique contrivance and certainly has many excellent features to recommend it. Prof. Pennington of Chicago, has devised a shield of metal which is clasped around the X-ray bulb; this shield has a cylindrical prolongation which can be used as a speculum or to which a speculum can be attached, and through which the rays are concentrated on growths in the rectum and vagina. The author reported three cases of cancer of the vagina in which he had employed the X-ray treatment in all of which there had been some varying degree of success, and states that at the present time in certain cases of cancer of the cervix, nothing short of complete removal should be attempted, but in the later stages of the same condition where the vaginal vault is involved and also the body of the uterus, it is highly improbable that more than temporary relief can be given the patient by surgical means, it would certainly seem that the X-ray treatment should be resorted to.

**Rational Treatment of Puerperal Infection.**—The opprobrium of our twentieth century medical science is the inconsistence of our teaching and practice regarding the prevention and treatment of puerperal infection, remarks H. G. WETHERILL (Am. Jour. of Obstet., May, 1903), for while its pathology and etiology are known the proper methods of prophylaxis for its control are not practised. The remedy at hand is the application of truly surgical methods to obstetrical procedures as in other surgical operations. Confinement in hospitals

should be advised, especially for those in moderate circumstances, with whom the proper aseptic handling is almost impossible at their homes. This will not only minimize the risks from sepsis, eclampsia and all other forms of dystocia, but all possible complications which may arise may be comfortably handled there by the surgeon. This writer insists upon the use of rubber gloves and fewer vaginal examinations as the true method of prophylaxis. The uterine curette does a vast amount of harm in all varieties of true septicemia, through the dissemination and distribution of the infectious material, and the opening up of new areas of absorption. The administration of an anesthetic adds not a little to the seriousness of curettage in that it gives extra work for a kidney already taxed to its limit. When the pulse is over 120 the patient should not be given an anesthetic. Of the vaginal and intra-uterine douches, but little need be said. The antiseptic solutions ordinarily used may do some good, but are capable of doing great harm if injudiciously or unskilfully used; we now possess better, safer, and more easily applied means to the same end. Antistreptococcic serum is mentioned, to be condemned along with unguentum Credé. Laxatives and purgatives are condemned as they weaken the patient, whereas the object to be sought for is one of stimulation. Whisky, caffeine, spartine, digitalis, quinine, are all valuable as sustainers, as is also adrenalin chloride, and may be used in conjunction with the other lines of treatment. The best results are to be obtained through the rigid application of the same methods as are employed in other intra-abdominal infections, with the additional use of drainage tubes and the intra-uterine irrigations of alcohol as advocated by K. Carossa, in 1896, and first brought to the attention of Americans by Dr. Ed. J. Ill of Newark, N. J., in 1897. Tubes and gauze may be left in situ from two days to two weeks, being kept free from obstruction with débris by the strong action of a good piston syringe. As to the results of the method, the author compared them to those witnessed some years ago in diphtheria from the use of antitoxin, for if it be instituted sufficiently early, that is, before general sepsis and diffuse peritonitis are established, the temperature, pulse and general expression of the disease were rapidly altered for the better, and even in one desperate case of general sepsis, with extensive embolic pneumônia and diffuse peritonitis, the patient recovered.

**Degenerations and Complications of Fibroid Tumors.**—The classical teachings concerning the life history of these growths, their degeneration, complications and dangers are far from correct, hence C. P. Noble (Am. Gyn., April, 1903) urges the necessity of a more careful study of these growths in order that they may be dealt with from a more scientific basis rather than from the old traditional standpoint. In estimating the risks encountered by patients suffering from fibroid tumor, there should be considered first those growing out of complications, which will be classified as follows: (1) Those which would lead to a fatal result; (2) those which would threaten the life of the patient; and (3) those which would involve more or less invalidism. It is difficult to estimate the number of patients that would die from the effects of hemorrhage: chronic anemia leading to degeneraton of the heart and kidneys; to pressure of the tumor on the ureters and bowels; to malnutrition induced by hemorrhage and by the increase of intra-abdominal pressure interfering with the functions of the alimentary canal; to the lowered vitality of the patients increasing their liability to intercurrent diseases; to septicemia from necrosis of the tumors; and to thrombosis through the associated phlebitis and to the subsequent degeneration of uncomplicated tumors. To these must be added the risks of pregnancy and parturition when complicated by fibroid tumors. Of 100 intra-abdominal operations performed by the author, 46 were unchanged fibromata, 2 showed telangiectatic changes, with non-encapsulation and abnormal diffusion through the muscle,and 52 presented pathological degeneration, 27 edematous or myxomatous, 1 myxosarcomatous, 5 cystic or fibrocystic, 1 calcareous and 18 necrotic. Pain, as a predominant symptom, is thought to be an indication of degeneration, it having been noted in two-thirds of the necrotic cases, in three-fifths of the cystic cases and in one-third of the myxomatous cases. The age of the youngest patient operated upon was twenty-three years, the oldest sixty-three and the predominance of cases was between the ages of thirty-five and forty-five years. An analysis of 668 cases of fibromata in the hands of four surgeons shows a mortality as follows: Martin, 16 per cent.; Noble, 16 per cent.; Frederich, 23 per cent.; Cullingsworth, 24 per cent. These are cases in which there was degeneration or complication without operation. No instance of a fibroid having disappeared after menopause has come under the author's notice. One case, seen fifteen years ago, was said to have lessened after pregnancy. It is a conservative statement that one-third of the women having fibroid tumors will die if they are not operated upon. The mortality from myomectomy varies between 2 and 10 per cent. depending upon the operator, the gravity of the case, the environment and upon the operation performed. It seems a fair conclusion that those resorting to an early operation will save from 30 to 35 per cent. in mortality. It seems to the author that the attitude of the text-books should be changed or reversed, and the rule should be to remove all fibroids that come under observation, unless, in a particular case there seems to be reason for temporizing, either because of the small size of the tumor or the advanced age, or to the general health of the patient.

**Veratrum in Puerperal Eclampsia.**—In this disease the convulsions occur very suddenly and without warning. The patient may suddenly cease speaking, the eyelids begin to twitch, the eyes become fixed or roll from side to side, the muscles of the face or the extremities jerk. The tongue may be badly bitten, the muscles of respiration may be involved in the spasm. The face is bloated, dark-purple, the features distorted, and the picture is a terrible one for the beholders. One attack follows another in quick succession. If dropsy occur or albumin appears in the urine during a pregnancy the patient should be kept in bed on a milk diet. Basham's mixture may be given with advantage. When the convulsion occurs there are two indications: elimination of the poison and sedation. The plan of J. S. Hammond (Ann. of Gyn. and Ped., June, 1903) is to control the convulsion by chloroform inhalation, give a hypodermic of 10 to 15 drops of tincture of veratrum viride, and examine bladder and rectum. Repeat the veratrum every twenty minutes till the pulse is below 60. The veratrum acts as an emetic and diaphoretic, and, in addition, the bowels may be moved by one-quarter grain of elaterium mixed with butter and placed on the back of the tongue, or by two or three drops of croton oil in a teaspoonful of olive oil. Hypodermoclysis will promote diuresis. Obstetric interference is not justifiable, for though the child may be the predisposing cause of the eclampsia it is not the exciting cause, and the hurried operation only adds to the existing toxemia, the dangers of irritation and traumatism. Leave delivery to nature whether the child is dead in the womb or not.

**A New Speculum**—An example of the villainies of special instruments is furnished by a new self-retaining vaginal speculum, suggested by S. Spiegel (Centralbl.

f. Gyn., June, 1903). Without describing the details of the device, it is sufficient to point out the one feature which the inventor thereof seems to have totally forgotten. It consists, briefly, in a speculum which is fastened rigidly to the table by a series of arms and clamps. It would need only a struggle on the part of the patient during imperfect anesthesia, to do herself incalculable damage. It is really strange that ingenuity enough to devise such an apparatus should not be accompanied by common sense to see that the dangers far outweigh the advantages of the invention.

**Ectopic Gestation.**—Formerly considered to be a very rare condition, the trend of modern thought is toward the opinion of an almost constant relation between ectopic gestation and pelvic hematocele. J. H. Stealy (Am. Gyn., May, 1903) believes that the trouble lies chiefly in the different views on the relation between these two troubles. If most of the blood extravasations in the pelvis are to be considered to be the effects of tubal pregnancy, then, indeed, the cases will be found to be very numerous. The only right that we have to call a pelvic hematocele a result of an extra-uterine pregnancy, is the absolute identification of decidual cells or chorionic villi, or the presence of a fetus. In a disappointingly large number of women it is impossible to get any suggestive history that might help us in solving the problem of etiology. And in the consideration of this question the author assumes as facts, a priori, that: (*a*) impregnation normally occurs in the fimbriæ of the tubes as shown by Strassman, Mandl, Hofmeier, Heusen and others; (*b*) the ciliary currents are downward from the fimbriæ to the cervix, as stated by Kelly; (*c*) the denudation of the epithelium of the uterus or the tubes is not necessary to the implantation of an ovum (Dudley). The more the subject is reviewed the more evident is the fact that we can lay at the door of no cause the fault of this condition. Broadly stated, any condition which absolutely prevents the egress of the impregnated ovum from the tube, or delays its passage until by its rapid growth it has become too large and heavy to be moved by the action of the cilia and the peristalsis of the tube, is a condition favoring tubal pregnancy. These conditions may be extrinsic or intrinsic, or acquired or inherited. The woman may have all the signs of pregnancy except the absence of her menses, and this should put us on our guard; or she may state that her menses had stopped for a month or so, and that she considered herself pregnant, when upon the re-establishment of the flow she believed herself mistaken. The symptoms of tubal rupture and abortion are those of pelvic hematocele and consist of all the evidences of severe internal hemorrhage and shock. When the rupture be into the cellular tissue of the broad ligament, the pain and shock will be intense. If a small vessel alone be lacerated the fetus may die and the patient go on in perfect health with a diagnosis of colic. In general, we may say that the etiology, signs, symptoms and treatment are as follows: Cases of ectopic gestation are by no means infrequent, and are among the most serious conditions with which we have to cope. Generally they occur in those near middle life, having a previous history of sterility. The symptoms that are to be carried in mind are: (1) The woman will have missed a period; (2) colicky pains; (3) bloody discharge from the vagina or an irregular continuation of menstruation, often leading the woman to believe herself pregnant. With few exceptions and these are dependent only on the woman's welfare, the indication for immediate operation in these cases is absolute. No case of "colic" in a woman capable of procreation, more especially one married, should be allowed to pass unscrutinized, without the thought of ectopic gestation in mind. And to be emphasized a thousandfold, is that no such symptom in a pregnant woman should be lightly regarded. Even though in many hundred cases, as it will be, our care results in nothing but a transitory diagnosis that passes through our minds, yet some time, to some woman, it may mean her life.

**Gonorrheal Puerperal Fever.**—In summarizing the chief essential points regarding this condition, Fred. J. Taussig (Am. Gyn., April, 1903) gives the following as the most important. The gonococcus is the etiological factor in about one-sixth of all cases of puerperal infection. Although secondary to a gonorrheal infection elsewhere, this trouble involves an infection of the puerperal wounds; and hence must be classified under the head of puerperal fever. The gonococcus may gain access to the uterine cavity without any internal examinations being made. Many a case of so-called autogenous infection may be explained in this way. More frequently the process is brought about by digital manipulations and operative procedures, particularly intra-uterine, in the delivery of the child and the placenta. The infection shows itself about the fifth or sixth day postpartum, by rigors, a temperature of 103° F., and a severe abdominal angina. The fever is usually of short duration, and the further course of the disease is mild, but liable to become chronic. The cases in which the temperature begins to rise as early as the sixth day, and runs up to 103° F. or more, are not necessarily caused by a mixed infection, as Baum and others hold, but are due to the gonococcus alone. The diagnosis is based on the rather late onset, the slow, regular pulse, the moderate and steady elevation of temperature, the profuse purulent, glairy, discharge, and, above all, by the presence of the gonococcus in the lochia. The prophylaxis is of more benefit than treatment. All pregnant women having gonorrhœa should be delivered without internal examination. Treatment should be limited to one or two intra-uterine douches, frequent vaginal irrigations and rest in bed for a prolonged period of time.

**Accidental Perforation of the Uterus.**—This accident is of far more frequent occurrence than is commonly believed, according to Abram Brothers (Am. Gyn., April, 1903). Cases occurring in the hands of midwives, professional abortionists and ignorant persons generally, in the effort to interrupt pregnancy, are frequently seen by physicians connected with public hospitals, consultants in gynecology, and the medical assistants of the coroner's office. But the large majority of cases which occur in the course of legitimate work and in the hands of honest practitioners of medicine never see the light of day because of the fear of criminal prosecution, or, at least, of public ridicule, even cases which do not go on to fatal termination. As a matter of course and fact, the author is convinced that it is the rare exception that uterine perforation ends fatally. In the treatment of these most unfortunate cases we must consider them in groups or sets. The first set of cases are those in which, during the passage of a sound or curette, the uterus is perforated. These cases will usually get well if manipulations are immediately brought to a close and if no irrigation is employed, intra-uterine in nature. If the uterus has been injured and the operator has irrigated the uterine interior, three sets of conditions may arise. In the first set a mild peritonitis (local) may call for nothing more than the same line of treatment. In the second set an acute septic peritonitis may call for an immediate hysterectomy (usually vaginal) with drainage per vaginam. The third set may be less virulent and more chronic. They are apt to terminate in localized abscesses which may be located in the pelvic tissues or in the pelvic

peritoneum. The operation in the majority of these cases will be in the nature of an exploratory laparotomy. In those cases in which the uterus has been injured and the intestine has been dragged through the wound, laparotomy must be done as early as possible. If the strangulation has been fatal to the vitality of the gut it must be exsected at once. The uterus may then, according to the judgment of the operator, be repaired or removed. Miqual reports five such cases, which were not fatal. Hysterectomy and curettage should be less resorted to in the large proportion of these cases, and recovery will be increased in percentage ratio.

**Vesicofixation of the Uterus.**—Retrodisplacement without adhesions, persisting after earnest and careful treatment and producing symptoms such as backache, dragging sensations and neuralgia, increased by slight exertion, as walking, chronic constipation and intense dysmenorrhea, are, according to N. J. Hawley (Am. Gyn., May, 1903) best relieved by vesicofixation. The operation is not contraindicated by the presence of a hymen. It is far superior to the Alexander operation in that it allows inspection and thorough examination of the adnexa. Endometritis, which usually accompanies these cases or any other existing abnormalities of the external genitalia, can be treated and relieved at the same time, thus obviating a second operation or the inconvenience of changing position necessitated by abdominal section. The lessened danger to the patient, shorter time in bed and absence of visible scar should also be taken into consideration. After the patient has been carefully prepared for the operation in the usual manner, the following steps are to be taken in performing the vesicofixation. With the posterior retractor in place, the cervix is grasped in a double volsella and drawn down as far as possible and the uterine sound passed to note again the exact position. A tenaculum forceps or Senn's forceps now takes hold of the anterior wall in the median line and stretches it out and away from the cervix. The incision is started just below the forceps and 4 or 5 cm. away from the cervix, extending to the latter and down to the bladder-wall. The vaginal mucosa is now dissected back on both sides, a distance of 2 or 3 cm., and also separated from the bladder where it joins the uterus. This union is divided with the knife or scissors and the bladder quickly pushed off and away from the uterus with the finger or a sponge on a forceps. The hemorrhage ensuing is slight and easily arrested. When the peritoneum is reached it is better to continue the pushing and separate the peritoneum well back from the top of the bladder before opening it in front of the uterus. After opening this membrane transversely, the vesical portion is seized by forceps and held forward, while two fingers are introduced for exploration. A long Pean's retractor is now inserted anteriorly to press forward the bladder and peritoneum, the cervix is released and pushed upward while the body of the uterus is grasped with two-pronged tenaculum forceps as high as possible and drawn forward. Another pair of forceps are applied higher up, the first removed and this continued until the fundus uteri appears at the peritoneal opening. Upon pushing the fundus to the right, the left tube and ovary may be drawn down and inspected, and likewise the opposite side. With the fundus held firmly by the forceps and drawn down, the peritoneum from the bladder is brought back and over it as far as possible, where it is sutured between the tubes with a fine continuous chromicized catgut and any excess of peritoneum removed. The edge of the bladder, first separated from the uterus, is stitched high up on the anterior surface of the uterus and with a single chromicized mattress suture. The two edges of the vaginal wound are now carefully approximated with interrupted catgut sutures, passed just deep enough to exclude hollow spaces. The bladder is catheterized and a loose vaginal packing of plain gauze is inserted. The object of the operation is to leave the uterus in an easy position of slight antiversion, therefore care should be exercised not to suture the peritoneum too far back upon the uterus; likewise, vaginal fixation is not applicable to these cases unless after menopause, and should be resorted to only for complete prolapsus.

**Puerperal Hematoma** is of very rare occurrence and it would require the aggregation of several hundred cases of labor to arrive at the exact truth of its frequency, according to H. R. Coston (Am. Jour. of Obstet., April, 1903). The predisposing cause is the engorged condition of the pudendal vessels and the strain put on them by labor; and to this may be added any pathologic condition of the vessels, such as sclerosis and varicosities. The exciting cause in most cases is the pressure of the fetal mass on the soft parts of the mother. The use of forceps or other instruments; symphyseotomy, or spontaneous separation at the symphysis pubis; the rapid delivery of the after-coming head; or the accidental striking of the parts against a hard substance. The vast majority of cases occur during labor, though it may take place after labor is terminated. When it is caused by injuries during labor, such as sneezing, violent coughing or the act of quickly sitting up in bed, has caused to dislodge a thrombus, and thus bleeding takes place. It may occur in any position, though usually it is in either of the labia majora. If the effusion occurs above the pelvic fascia it forces itself upward; if below the pelvic fascia it dissects toward the vulva. Pain may be more severe in a small hematoma that is stretching the skin, than in a large hematoma which is subperitoneal. If the amount of blood lost is great, there will be present, besides the signs of hemorrhage, pain proportionate to the amount of the hemorrhage and to the location of the blood. To the eye, the tumor is blue or bluish black in color, depending upon whether it is under the skin or mucosa. Should a hematoma rupture while the hemorrhage is in progress—especially if it should rupture intraperitoneally, all the symptoms of hemorrhage would rapidly increase, and unless the attendant quickly made use of radical measures, the patient would soon bleed to death. Should the hematoma become infected, there would be symptoms of suppuration added, with the production of metastatic abscesses. The condition of hematoma must be diagnosed from varicose veins in the vulva, hernia, inversion of the uterus, or vagina, blood clot, the placenta, or a fecal mass in the rectum. Formerly, hematoma was regarded as a very serious trouble, the death rate being from 20 to 40 per cent. In this day of asepsis it should not reach seven per cent. In all cases the bowels must be kept open; the diet must be light, but nutritious; the woman must have stimulants, tonics and alteratives as the case demands, always remembering to keep the stomach in a healthy condition. The skin and kidneys must be watched for septic processes. In failure of nutrition, in long continued cases, some preparation of malt or beer are to be recommended. Those cases occurring before delivery will receive the same treatment as those afterward, except that it may be necessary to incise the tumor to remove the obstructing mass.

**Cystic Bladder Mistaken for an Ovarian Cyst.**—With the diagnosis of an ovarian cyst, a colored woman, about forty years of age, was admitted to the wards of Enrique Fortune (Am. Jour. of Obstet., April, 1903). There was a tumor of the abdominal cavity, cystic in character and about the size of a man's head,

There was bulging of the tumor in the lower abdominal segment, and it was centrally located. Its relations with the uterus could not be appreciated. It was somewhat movable. Diagnosis of ovarian cyst was made. There was repeated frequent micturition of small quantities, but the total amount excreted was normal. Operation was decided upon, and on opening the abdomen the cyst came into view and all efforts to withdraw it were ineffectual. Incision into the cyst brought forth a watery liquid. The internal surface of the cyst seemed so much like that of the bladder, that an assistant was instructed to catheterize the patient. A small amount of urine, bloody in character, and this with the fact that the catheter could be felt beneath the hands of the operator, assured him that the tumor was of the bladder. On a second catheterization of the bladder, the lip of the catheter was brought out of the abdominal wound. The lacerated portion of the vesical sac was resected with scissors and then sutured in two continuous planes. The abdominal wound was closed without drainage and a self-retaining catheter was introduced into the bladder and left there for nine days, after which time the urine was voided naturally and spontaneously. There was no urethral or vesical irritation. Convalescence was rapid. Inasmuch as the uterus was found to contain a large fibroma and hysterectomy was necessary, it was evident that the bladder was bent and compressed by the fibroma; the superior portion communicating with the inferior one, emptied itself incompletely until the time when the exaggerated flexion of the bladder shut it off entirely from the lower portion, thus establishing a permanent cyst. As the ureters voided into the lower portion of the bladder, no derangement took place other than the frequent micturition due to the reduced capacity of the bladder. The urine contained in the cyst lost its characteristics as a hydronephrosis, becoming watery.

## PHYSIOLOGY.

**The Irritability of the Brain during Anemia.**—When the brain is subjected to anemia by the process of perfusing solutions, such as Ringer's solution, its functions soon cease, according to W. J. GIES (Amer. Jour. of Physiol., May 1, 1903). When anemia is induced rapidly, convulsions ensue. When gradually induced, anemia may be made acute without causing the appearance of convulsions. When anemia is produced gradually, the functions cease usually in the following order: (1) In cold-blooded animals: respiration, skin reflex, lid reflex, nose reflex, heart beat. (2) In warm-blooded animals: lid reflex, respiration, nose reflex, heart beat.

**The Growth and Histogenesis of Nerves.**—There are four stages in the development of nerves, according to C. R. BARDEEN (Am. Jour. of Anatomy, March 28, 1903). They are as follows: (1) The differentiation of motor nuclei and sensory ganglia. (2) The outgrowth from the central nervous system to various peripheral anlages. (3) The development of branches from the principal nerves, etc., various parts differentiated from these anlages. (4) The development of functional unity between the nerve fibers and the structures to which they are distributed. The proximal nerve plexuses are formed during the second period, the coarser peripheral plexuses during the third, and the finer peripheral plexuses during the fourth period. During the last three periods there may be considerable shifting in relative position of the structures to which the nerves are distributed. The union of nerve and muscle fibers takes place before the formation of the sarcolemma. The terminal apparatus of the nerve is more resistant to digestive fluids than the muscle substance, and is closely attached to the under surface of the sarcolemma. The sheaths of the nerves serve to maintain the stroma in which the axis cylinder fibrils grow. Myelinization is due to influences exerted by the axis cylinder fibrils on the surrounding stroma.

**Oxalic Acid and Oxaluric Acid in the Urine.**—There frequently occurs, according to A. M. LUZZATTO (Hoppe Seyler's Zeitsch. f. Physiol., Vol. 37, No. 3), in the urine of dogs and in small amounts in human urine, a substance which on boiling with hydrochloric acid, yields oxalic acid. This substance in all probability is oxaluric acid. The addition of ammonium oxalurate to human urines does not produce, even after a long interval, a sediment of calcium oxalate. This argues against the hypothesis that the occurrence of this sediment in urine depends upon the presence of oxaluric acid. Under certain, as yet unknown, conditions, less oxalic acid is found in urine boiled with hydrochloric acid than in unboiled urine, a circumstance of practical importance in the technic of the determination of oxalic acid. The administration of uric acid produces no noteworthy increase in the elimination of oxalic acid. One need not conclude, however, that oxalic acid is not formed in the organism out of uric acid, since it might be formed by the oxidation of the latter. Oxaluric acid is changed in the animal's body into oxalic acid and completely oxidized.

**The Lecithanes and their Physiological Significance.**—The group of bodies extracted from brain-substance, including lecithin, cephalin, myelin and others, and now classed under the name "phosphatids," should, according to W. KOCH (Hoppe Seyler's Zeitsch. f. Physiol., Feb. 5, 1903) be included under a general group which he calls "lecithanes." These are defined as waxy hygroscopic substances which are built up out of orthophosphoric acid, the higher satisfied and unsatisfied fatty acids, nitrogenous groups and glycerin. The author's investigations have led him to the conviction that the physical as well as the chemical properties of the lecithanes are of great significance for the life of the cells. The capacity of lecithin to mix with water, has been known for a long time. With water it forms a colloidal solution that cannot penetrate parchment paper. It is not precipitated by the univalent kations of Na, K, $NH_4$, Li and Ag, even in concentrated solution. The salts of the bivalent kations Mg, Ca, Si, Co, Ni, Fe″, Zn, Cd, Cu and Pb produce a gelatinous precipitate. The salts of the trivalent kations act like those of the univalent; they are the salts of Fe‴, Al and Au. The anions Cl, Br, I, $SO_4$, Citrates, Oxalates and Ferrocyanides behave like the univalent kations. The non-electrolytes, albumins, peptones, glucose, urea alkaloids like caffeine, aconitin and strychnine and narcotics like urethan and chloral, have no effect on the solution. Chloroform is emulsified in the presence of the colloidal solution. Very remarkable is the influence of the univalent and trivalent kations upon the precipitation brought about by bivalent kations. In the presence of a slight excess of Ca, only a small amount of Na is necessary to inhibit the precipitation. All the above facts indicate that, as regards lecithin, it is not a question of chemical reactions but one of precipitation phenomena, probably of electrical nature. If the life of a cell depends, as Quincke and Loeb maintain, upon the condition of the colloids or their viscosity, it may then easily be seen how the antagonistic effect of the precipitate-forming calcium upon the dissolving sodium, would produce the correct viscosity necessary for a living cell. Too much sodium or too much calcium disturbs the equilibrium and the cell ceases to live, and the addition of the correct amount either of calcium or of sodium, renders possible the continuance of the life-process. The observations made by Mathews

on the effects of anions on motor nerves afford an inexplicable contradiction to the absence of any influence of anions on the solutions of lecithin. As regards the chemical properties of the lecithanes, one may look upon the constituent unsatisfied fatty acids and the nitrogenous group as those portions of the atomic complex that take part in the metabolism of the cell, the former being related to the oxidative processes. The nitrogenous group of lecithin is, according to Halliburton, of physiological significance, since, in certain diseases of the nervous system (*e.g.*, paralysis) large quantities of cholin pass into the cerebrospinal fluid. The fact that cephalin unlike lecithin has one methyl group, indicates that the former is probably an intermediate metabolic product of the latter.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**The Medicolegal Tests of Blood Stains.**—The identification of human blood stains has become one of the chief problems of forensic medicine. All differential methods are along two lines, tests based upon microscopic findings, and those based upon processes which may be based upon test tube reactions. Some further confirmatory experiments with the serum tests have been made by E. N. Layton (Am. Med., June 6, 1903). The serum was secured from rabbits. The author believes from his experiments, which cannot be detailed here, that the reaction observed is caused by the development within the blood serum of the injected animal of an antibody or a property or substance which causes a certain reaction with the serum homologous to the one injected. The reaction does not occur when normal rabbit serum is used. The reaction occurs much more rapidly, especially when dilute solutions are used, if the test is exposed to a temperature of 37°C., although it will occur at ordinary room temperature. Only the minutest stain and a single drop of the test serum is necessary for making the test, and its delicacy is not altered by the admixture of other bloods or of foreign material, except the albumin precipitates, nor by the age of the stain. A differentiation from monkey blood is possible by great dilution of the blood tested and a dilution of the test serum of 1-500, with incubation; also by a great dilution of the blood tested, the test serum being used pure at room temperature. The test is specific, invariable, and therefore applicable to forensic use. No difference could be detected in the reactions between the blood of white and colored persons.

**Roaches as Conveyors of Typhoid.**—A localized epidemic of typhoid fever in Chicago was believed to be due to the portage of infectious material by the ordinary cockroach, according to the statement of R. Engelmann (Medicine, June, 1903). Investigation of the large apartment house in which the epidemic occurred, showed certain apartments overrun with these vermin and here the cases of typhoid were found. When the roaches were completely exterminated no further cases developed. The author recommends in all cases that sulphur fumigation is indicated as supplementary to formalin disinfecton.

**The Bacillus of Typhoid in the Blood.**—A series of blood cultures have been made upon typhoid fever patients to determine the relative frequency of the bacillus of that disease in the blood, by Herbert Fox (Proc. Path. Soc., Phil., May, 1903). The blood was taken from undoubted cases from the median basilic vein by aspiration and mixed with agar-agar. In this way fourteen cases were examined and the results of the cultures showed the *Staphylococcus epidermidis albus* present in five cases, this and the *Staphylococcus pyogenes albus* in one, the *Bacillus typhosus* and the *Staphylococcus epidermidis albus* in one, the *Bacillus coli communis* in one, a spore growing bacillus, probably air contamination, in one, and absolutely sterile plates in four, save for mold. The culture which showed the *Bacillus typhosus* was made at the end of the second week and did not appear until four days after the plate was made. To the late day at which the cultures were made may be attributed the fact that the bacillus was not found more often. The frequency of the other forms must be attributed to the imperfect sterilization of the deeper layers of the skin.

**The Effect of Small Amounts of Infectious Materials on the Blood.**—The injection of a very minute quantity (1/300 part of a "loop") of a living twenty-four-hour typhoid culture into the veins of a rabbit was shown by F. Freymuth (Deut. med. Woch., No. 20, 1903) to exert a marked specific action on the blood. This shows how a very slight infection may have a most harmful influence on the blood-forming apparatus and may also explain how many chronic anemic conditions may depend for their continuance on a steady resorption of minute quantities of bacterial toxins.

## THERAPEUTICS.

**The Value of Theocin as a Diuretic.**—This lately introduced diuretic remedy has been compared in a series of clinical tests with agurin, diuretin, and a number of other drugs, by H. Kramer (Münch. med Woch., March 31, 1903). The cases were all marked by ascites or general edema and the drug was given in five grain doses, three to five times daily. The effects were noticed quite soon after administration, from less than one to six hours. The maximum effect was observed on the first or second day of the administration, and as long as it was continued no diminution was seen of its effects. The blood pressure did not appear to be influenced in any way and no disturbances of the nervous system were observed. The only unpleasant after-effects were frequent nausea and vomiting. The author concludes that the remedy is a valuable and rapidly acting diuretic which rarely fails and is more powerful than either agurin or diuretin. It is desirable, however, to attempt the making of a preparation which shall be less productive of nausea and vomiting.

**Potassium Iodide in Migraine.**—The employment of this drug in many cases of so-called sick headache is highly recommended by J. R. Clemens (Therap. Gaz., May 15, 1903), who uses it to the exclusion of all other remedies. He was led to its administration by the observation that a great similarity existed between migrane and cerebral syphilis, the headache of both being characterized by pain that is deep-seated, constricted, of great intensity, with nocturnal exacerbations, long durations, and relapses. There is also present raised arterial tension. The author found that in the most aggravated cases, potassium iodide in 5 to 15 gr. doses, three times daily, diminished both the frequency and severity.

**Value of Alcohol in Infections.**—A preliminary note on some experiments to determine whether alcohol does good in infections by increasing the bacteriolytic power of the blood, is published by H. A. Hare (Therap. Gaz., May 15, 1903). The experiments were conducted in typhoid and also in a number of chronic cases, including nephritis, tubercular peritonitis, etc. It is apparent from the results obtained that the use of alcohol seems to have the power of combating infectious diseases by increasing the bacteria-desrtoying power of the blood. As far as they have gone, the experiments indicate that the effect is produced to some extent at least by an increase in the complement.

# The Medical News.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## A HOPEFUL OUTLOOK.

It is with a feeling of enthusiasm that we present to our readers this week the paper by Dr. Maragliano, which has come to us fresh from the Congress at Madrid, and which gives us the result of his experiments in "The Struggle of the Body against Tuberculosis, and its Immunization."

As Jenner took the hint that led to vaccination as a means of immunization against smallpox, from a milkmaid who stoutly claimed that she could not take smallpox as she had already had cowpox, so Maragliano has developed the idea of an inoculation against tuberculosis from the well-known observation, as common and as simple as that of the milkmaid, viz., that many people, as is shown by autopsies and clinical histories, have tuberculosis, and get well of themselves, and never have a recurrence.

He holds and apparently proves that the human body contains within itself the power of exerting a potent counter-influence to the tubercle bacilli. The steps by which he proceeds in determining and intensifying this antitoxic element are ingenious, and marvelous in the exhaustive series of experiments by which he establishes a unit of test to determine exactly the effect of treatment on animals as well as on man.

When he declares that for eight years he has been able to effect a cure of tuberculous cases by means of the injection of the serum of immune animals, we are convinced of the genuineness of his clinical success. When he announces that he has at last succeeded in preparing a material which, all danger of infection being excluded, will cause, when inoculated under the skin, a tuberculous abscess, and which will render a man immune to tuberculosis, we echo his wish that there "may yet remain enough of life to him to see this conquest of science brought to an end."

Such men as Arloing, Behring, Koch, and notably Trudeau in our own country, have all contributed to the end which Prof. Maragliano believes that he has reached. If the salvation of humanity is at hand, no one is without honor, but after such earnest striving for such a glorious goal, we feel that Maragliano and his coworkers will win for themselves the satisfaction of having given hope to the race.

## THE TUBERCLE BACILLUS AND NUTRIMENT.

Nearly ten years ago Dr. E. A. de Schweinitz in the course of investigations undertaken in connection with his work as government expert at Washington, pointed out that the bodies of tubercle bacilli are rich in substances of a fatty or waxy character which can be extracted when collected in sufficient quantities by means of ether and alcohol. His work was carried on in connection with Dr. Dorset and was published in the *Journal of the American Chemical Society*, August, 1895. The conclusions reached were confirmed by Behring and others in Europe, who showed that the greater part of the bodies of tubercle bacilli, when obtained in large quantities in bouillon for the special purpose of analysis is composed of this fatty or waxy material. These investigations referred only to tubercle bacilli of human origin, but seemed to point out that only conditions in which the tubercle bacilli could obtain fatty material for its nutrition readily would make a suitable environment for the rapid growth of the bacilli.

We pointed out some years ago that these observations seemed to furnish an explanation of two facts that had been noted clinically for many years, but of which no complete explanation on clinical grounds was forthcoming. It is in persons who are under weight as is evident by clinical experience and by the attitude of insurance companies toward those who are below the normal weight and in individuals who are rapidly losing

weight that the tubercle bacillus grows with special luxuriance. On the other hand it is well known that as soon as patients begin to gain in weight the previous growth and tendency to dissemination of the tubercle bacilli in their tissues comes to a halt. In a word, there is a distinct connection between the condition of the fat contents of the patient's tissues and the tendency to tuberculosis.

When patients are losing weight, fatty material is being taken up from portions of the body where it was previously deposited and is finding its way through the lymph channels into the veins in order to be used up on the arterial side of the circulation in the presence of the oxygen from the lungs, for it is by oxidation processes that fat is burned in the body. When the fat thus being carried in the venous blood is on its way through the lungs, it evidently furnishes a plentiful supply of fatty material for the growth of the tubercle bacilli that may be present. Unless the tubercle bacillus can obtain this fatty material thus abundantly it cannot grow luxuriantly. On the other hand, when fatty material is being deposited in the body tissues, there is an absence of fat products of suitable nature for the nutrition of the tubercle bacilli in the venous blood that passes through the lungs and consequently a condition develops unfavorable to the further growth of tubercle bacilli.

Since his original observations on the composition of tubercle bacilli, Dr. de Schweinitz has made a similar set of analyses upon tubercle bacilli derived from swine, the horse, the bird, cattle and various attenuated and virulent forms of human tubercle bacilli.

While there is considerable difference in the amount of soluble matter in these various germs, there is enough of similarity to indicate that they belong to the same family. The differences that exist, however, are suggestive, inasmuch as the virulent human germ appears to be more closely related in its composition to the bacillus of bovine tuberculosis than to any other, just as the attenuated human germ appears to be more closely related to the avian bacillus of tuberculosis, which is, so it is thought, not pathogenic for man, though it can be made pathogenic by Nocard's method of growing it for a while in collodion sacs in the peritoneal cavity of certain susceptible animals.

In his article, read before the Climatological Association, last year, Dr. de Schweinitz suggests (Transactions of the American Climatological Association, Vol. 18, 1902) that the composition of these various germs is instructive in showing us that the bacilli utilized those constituents of the animal body, which are very important for life and health. He adds that it is not unreasonable to believe that this unnatural waste could be offset by food which would supply the material especially desired by the bacteria, so that the natural processes of life should be balanced and the organism able to protect itself from the attacks of disease producing bacteria. The hitherto empirical use of fats in the treatment of consumption is thus given an experimental explanation. Nuclein and lecithin, which have also been suggested on theoretical grounds apart from the composition of the tubercle bacilli, would also seem to be indicated in order to make up for the increased consumption of these substances due to the growth of the tubercle. This method of dietetic treatment would as can be seen constitute a direct antidote to the specific "consumption" of material that causes the general breakdown, and hence has caused the disease to be called, so appropriately, phthisis or consumption.

Since the tubercle bacilli are on varying culture media susceptible of great changes, not only morphologically, but in their specific virulence, which is in direct ratio with the favorableness of their surroundings, diet may actually modify the character of the tuberculosis in a given case and make it more tractable. This bacteriological substantiation of the old dietetic treatment will encourage still more the ever growing number of those who, in recent years, have been practically abandoning drugs and especially all notion of specific indication to insist upon fresh air and food as the only real remedies for tuberculosis.

---

## FOURTH OF JULY TETANUS.

THE present issue of the MEDICAL NEWS bears the date July 4, and although we feel that the subject is hackneyed, yet the crop of deaths which signalizes our inevitably recurring annual epidemic of tetanus, as a consequence of the celebration of the Glorious Fourth, should not be allowed to pass without a word. Already the Board of Health of Chicago has reported a series of deaths from tetanus occurring in wounds caused by fireworks, or firearms, bought in anticipation of the noisy celebration.

We cannot hope that good sense is to prevail in this matter and so physicians must be especially mindful of every possible prophylactic precaution in the treatment of wounds that come under observation about this time and likely to be

contaminated with street dirt. As pointed out by the municipal health authorities of Chicago, a number of patients who have died have been treated by physicians from the beginning, and, sad to relate, have not all been treated by such methods as are best calculated to minimize the danger of tetanus infection.

It is now too well known by physicians to need repetition that the tetanus bacillus is absolutely anaerobic and will not grow in the presence of the free oxygen of the air.

It is almost as constantly present in street dirt, contaminated as that always is by horse droppings as it is in the dirt of farm yards, which seems to be its usual habitat outside animal bodies. Tetanus would be much more frequent, only for the fact that in open wounds the bacillus will not grow. In the seared wounds made by the burns of fireworks, toy pistols or the like, if the tetanus bacillus gains an entrance it is likely to be placed under favorable conditions for growth, because of the rapid sealing process on nature's part that follows in the attempt at repair of a burn.

The physician's duty in the matter, then, is to lay such wounds open if necessary and keep them open as far as possible rather than to encourage rapid healing. Many other therapeutic measures have been suggested but few have proved worthy of confidence. Cauterization instead of acting as a prophylactic would probably add to the danger by causing superficial coagulation necrosis of tissues beneath which the tetanus bacillus finds a favorable culture medium away from the oxygen of the air. Antitetanic serum has lost the confidence of the profession, at least when used in the later stages of the disease. After all it is not surprising that tetanus antitoxin should prove a failure, since the first manifest symptoms of tetanus are, as has been well said, not the preliminary signs of the disease, but the first warning of fatal intoxication from tetanus. The toxins of this fatal affection have already become inextricably associated with the nerve cells of the patient and there is little hope for relief.

There still remains the possibility of antitetanic serum proving useful if administered shortly after the infliction of the wound. In this case any tetanus toxin present is neutralized and a condition of the fluids of the body set up which is unsuitable for the growth of the tetanus bacillus. Prophylaxis must be a watchword and this can be best accomplished by encouraging free bleeding and preventing, as far as possible, any precocious closure of wounds that have been contaminated by street dirt. The precautions are worthy of careful attention since, according to recent statistics, tetanus has been calculated to carry off each year about 30 to 40 per million of the population of large cities.

### WHO IS RESPONSIBLE?

Governor Odell very naïvely remarks in a recent contribution to the daily press, that "in a recent visit to the institutions there was not disclosed the horrible state of affairs which has been set forth by some sensational writers in the public press," and adds, "it may be that the true situation of affairs was so concealed from him that he was unable to discern it." Perhaps the Governor inspected the Randall's Island Institution for Juvenile Delinquents in much the same manner in which he made an inspection of the State Hospital sometime in the past year—the results of which were embodied in one of his messages to the legislature.

We can well imagine the Governor did not see anything out of order at Randall's Island when his strabismic report on the conditions in the State hospitals is borne in mind, in fact, myopia seems to be the Governor's chief stock in trade in this particular phase of his duties. It is all very well to attempt to saddle the responsibility of the conditions on Randall's Island on President Orr's shoulders, but unless it can be shown that a comprehensive and thorough knowledge of the State charitable institutions is possessed by our chief magistrate, we cannot feel that the taxpayers of the State believe that the interests of its charges are being looked after, from the true philanthropist standpoint rather than from the viewpoint of political graft.

## ECHOES AND NEWS.

### NEW YORK.

**New Regulation at Post-Graduate School.**—According to the annual announcement of the Post-Graduate Medical School, 639 physicians from various parts of the United States and Canada have attended the institution during the past season. The Faculty has instituted a new system, by which certificates of proficiency will be given to such doctors as attend the clinics for six months continuously and who pass a satisfactory examination on any one subject.

**Treatment of Dysentery.**—The forthcoming bulletin of the State Health Department will make the announcement that the State antitoxin laboratory will cooperate with the Rockefeller Institute this summer in a careful investigation into the treatment of dysentery. Local health officers called upon to handle an epidemic

of the disease this year are to be asked to notify the State Health Department in order that it may be investigated. The bulletin also will deal with the use of the tetanus antitoxin, which the department is prepared to furnish to health officers.

**Epidemic of Trachoma at Buffalo.**—Advices from Buffalo, bearing date of June 24, state that trachoma is becoming more and more prevalent in that city. According to the statement of an official of the United States Marine Hospital, more than 100 cases of the disease have been found among the employes of the Lackawanna Steel and Iron Company, and many have been treated by physicians in almost every section of the city. It is believed that the disease was brought by foreigners, who came into the country by way of Canada.

**Roosevelt Hospital Busy.**—The annual report of Roosevelt Hospital, which has just been made public, shows that the number of patients under treatment in the year 1902—3,874—was greater by 104 than in the preceding year, and the daily average of patients larger by 12 than in 1901. The number of cases treated in the emergency department was 8,339, or 281 in advance of any highest previous record. The report indicates that the two automobile ambulances in use by the hospital have proved to be somewhat unsatisfactory because they have become disabled so frequently. The remodelling of the ambulances is recommended. The record in the "out-patient" department shows an increase of treatments, which is considered an encouraging sign in view of the falling off in many of the dispensaries. The gifts in money to the hospital were few, the total amounting to only $5,113.31, while the expenses for the year were $172,593.62—$13,928.32 greater than in the previous year. The report calls attention to the urgent need of increasing the endowment fund by $500,000. Not a single bed was endowed during 1902, and that the annual deficit was kept down to $6,208.23 was due to the increase in patronage of the private patients' pavilion.

**Sale of Antitoxin by Health Board.**—Dr. E. J. Lederle, President of the Board of Health, sent to the Mayor last week a letter replying to a communication from Mr. Low regarding the manufacture and sale of antitoxin by the Department of Health. In this letter Dr. Lederle says that the production by the department of diphtheria antitoxin was begun, and arrangements subsequently made, so that physicians might obtain their supplies properly, and also so that in cases where the family of a patient was too poor to pay for the antitoxin, it should be given free by the Health Department. Some time after this went into effect, Dr. Lederle writes, a provision was inserted in the charter permitting the department to sell its surplus supply. Accordingly the department sold large quantities to persons outside of the city as well as inside its boundaries. This sale was due to the confidence felt in the purity of the antitoxin produced by the New York City Health Department. According to Dr. Lederle now, however, it is the expert opinion that there are other products of antitoxin on the market which are of as high grade as that prepared by the Health Department. Believing that the sale of antitoxin by the department to persons outside the city is contrary to the spirit of the charter, the doctor says he has informed such persons they must arrange to make their purchases of other producers after July 1. He goes a step further and suggests that hereafter the department shall dispense all its laboratory products free, as do other municipal and State laboratories upon receiving the proper requisitions from department officers or private physicians. Such distribution would, of course, be confined to residents of the city who may be in need of these products as a prevention of or cure for contagious diseases. Should this plan be adopted, and should the department at the same time stop its cash sales, between $20,000 and $25,000 annually will have to be supplied by the Board of Estimate in addition to the appropriation now current, of $49,748 for the maintenance of the laboratories. Mayor Low said he would submit the suggestions of Dr. Lederle to the Board of Estimate.

**A Righteous Decision.**—The Corporation Counsel's assistant, Matthew C. Fleming, brought suit in behalf of the Tenement House Commission against Katie Moeschen, the owner of the property, No. 332 East Thirty-ninth street, for a penalty for failure to comply with section 100 of the amended tenement house law relative to sinks in yards of premises occupied by more than three families. Associated with the defendant were the United Real Estate Owners' Associations, composed of more than seven thousand property owners. They set up as a defence that the law ordering extensive improvements and exposed plumbing was unconstitutional, because it was unreasonable, arbitrary, improper and unfair, while admitting that section 100 had been violated. After a trial lasting two days, in which much testimony was taken, the case was decided in favor of the department. It was a surprise, as the defendant had demanded a jury trial, and on the jury were a prominent builder, an iron merchant, a plumber and several owners of tenement houses. But after a three hours' discussion the jury brought in a verdict against the defendant. Having obtained a verdict of a jury that in their opinion the law requiring the removal of alleged unsanitary structures from the yards of tenement property is reasonable, the Corporation Counsel and the Tenement House Commission feel that their position is morally and legally much stronger than before, and they are ready to meet the appeal taken by Philip Bloch, the Real Estate Owners' Association's counsel. Experts testified that the unsanitary condition of structures facilitated the transmission of typhoid, diphtheria, cholera and tuberculosis. Plumbers and builders testified that to make the alterations demanded under the terms of the amended law would mean an expense of $750 and upward in nearly ten thousand cases. As the law applies to all structures in this city occupied by more than three families whose cooking is done separately, this decision concerns the owners of many apartment houses where the rents run from $30 to $40 a month, quite as much as it does the owners of tenements. Probably another case will be tried very soon in the Court of Special Sessions, according to Mr. Fleming, and whichever side wins the matter will be carried to the Appellate Division of the Supreme Court in order to get a decision at the October term. This will bring the adjudication of the matter close to the municipal election, and both sides feel that political capital will be made out of the affair.

**Manhattan Dermatological Society.**—A regular monthly meeting was held June 5, 1903, Dr. L. Weiss, presiding.

The following four cases were presented by Dr. W. S. Gottheil: (1) Lupus vulgaris; present since childhood; (2) Lupus erythematosum of five years' duration. Both cases subjected to Finsen therapy three times weekly for the past 2½ months, and both showing decided improvement. Dr. Cocks stated that Finsen therapy was of undoubted benefit in lupus vulgaris; in lupus erythematosus it was not so good a therapeutic test, since equally good results might be obtained with other methods; (3) a case of eczema seborrhoicum; patches of varying size, scaly, moist and friable, covered the entire body; under treatment the condition is improving; the case was considered typical; (4) congenital tertiary syphilis in a boy of eighteen years;

eruption of tuberculous and rupial patches were present for the past four years; no history of infection obtainable; hearing and sight are good; the right tibia shows "saw bone" contour. This case was regarded as specific, but the majority of the members believed it to be acquired rather than congenital.

Dr. L. Weiss presented a woman of fifty years, showing an irregular outlined ulceration at inner angle of left eye and adjacent nose and cheek; present about two months and of rather rapid development. Many years ago patient states she had an extensive ulceration along the right postauricular and occipital regions, which healed, and now shows in this region white, glistening, pearly scar tissue. Patient denies any infection. Believing it might be an acute outbreak of lupus, patient was treated accordingly with negative results. Under ung. hydrarg. ammoniatum, the ulceration is rapidly healing and to this circumstance Dr. Weiss now suspects a syphilitic taint. Dr. Gottheil said that the old scars on neck look like old luetic lesions; the acute process was too rapid in its course and unlike lupus in this respect. Dr. Oberndorfer considers it a superficial gumma; he also looks upon the old scars as specific. Dr. Kinch said rapid growth and tendency to get well under treatment mentioned favored diagnosis of lues.

Dr. B. F. Ochs presented a case with the following history: A young man applied a bandage saturated with carbolic acid (℥i to ℥viii) to both arms to relieve an acute hyperemia and itching; some pain followed and the bandages were removed within one hour, and soothing applications applied; though the pain was relieved, some soreness still remained and within twenty-four hours a ridge of blisters was observed encircling both arms and corresponding to the upper and lower limits of the bandages; from these there developed a circle of keloid; on the left arm the circle of keloid was complete; the right arm partially so and the circle completed by a ring of pigmentation. The phenomenon was unusual and could not be satisfactorily explained by Dr. Ochs. Dr. Weiss expressed the opinion that the carbolic solution plus a tight bandage might account for the development of keloid. Dr. Gottheil remarked that so weak a solution of carbolic could not produce sufficient loss of tissue and consequent keloid. Dr. Abrahams said he saw a great deal of harm result from even weak carbolic acid solutions; if patient was susceptible, loss of tissue may have taken place; the keloid could then be accounted for.

Dr. Ochs also presented (on account of its rare situation) a case of verruca, situated on buccal mucous membranes and at angle of lips.

The following cases were presented by Dr. R. Abrahams: (1) A case which he termed morphea: a circumscribed patch of scleroderma on left cheek, showing beginning atrophy at its outer edge.

Drs. Gottheil and Pisko could not recognize any scleroderma nor atrophy; they regard it as a simple edema. Dr. Oberndorfer believed it to be edema, probably due to involvement of the nerve filaments of the infra-orbital branch. Drs. Bleiman and Sohel termed it angioneurotic edema. Dr. Abrahams said the latter would not last for eleven years, coming and going; he recognized a resemblance to a variety of morphea described by Crocker. (2) Case of idiopathic atrophy of skin confined to right foot. It began as a patch of redness which faded away, leaving a patch of pigmentation; the process repeated itself until the dorsum of foot became involved; there is some thinning of the skin and pigmentation. It was believed by the members that the process was an eczematous condition, pigmentation being secondary; the appreciable thinning of the skin was not considered a true atrophy. Some varicose veins were observed, which were regarded by Dr. Oberndorfer responsible for the extensive and unusual pigmentation.

Dr. I. P. Oberndorfer showed a case of lichen planus obtusus, lesions confined to the right lower leg. (2) A case with the following history: Male, forty years old, was operated upon nine months ago for a right sciatica, since which time the right leg is anesthetic. About four weeks ago there appeared on the right foot an eruption characterized by central excoriation peripheral vesicles and bullæ with undermining of the cutis; process extended until entire sole and inner side of foot were involved; the loose cuticle being removed reveals a highly red inflammatory zone, dry and apparently in the process of healing. Dr. Oberndorfer believes in some connection with the nerve lesion mentioned and terms the condition trophoneurotic dermatitis. The majority of the members looked upon it as a traumatic dermatitis and probably independent of the pre-existing nerve lesion.

A third case by Dr. Oberndorfer was a typical case of sclerodermia; process began three years ago in the left hand; then the right hand, face and both feet in the order named; the fingers show clubbing and the nails atrophy. The parts are hard, tense and thickened. On thyroid extract recently, and patient shows some improvement.

**The Work of the Milk Commission of the Medical Society of the County of New York.**—The warm season is at hand when food is preserved with difficulty, and when deaths from summer diarrhea in infancy become numerous. Since many of these deaths are due to unwholesome milk, which is produced in dirty dairies, is never efficiently cooled and is very old when delivered to the consumer, such milk, on account of chemical changes and its myriads of bacteria, being unfit for infant feeding, the Milk Commission of the Medical Society of the County of New York would call attention to the inspected and certified milk produced under its supervision, the general use of which should tend to diminish materially this great factor in our death rate. The inspected milk is produced at dairies which are inspected at regular intervals by the inspector of the Commission. The stables are clean and are provided with facilities for cleansing the hands of the milkmen. The water supply, the milkers, the utensils, the cattle and the transportation are all subject to requirements necessary for producing a clean and safe milk. This inspected milk may be bought in bulk for institutions or in bottles for families at or about the same price as ordinary milk. Each bottle is covered by a cap marked "Inspected by the Milk Commission of the Medical Society of the County of New York." Certified Milk is a still higher grade of milk produced under very stringent rules. Thus, among other things, it is required that the dairies producing this milk should sterilize all bottles and other utensils and seal and date every bottle of certified milk. Certified milk is sold at a somewhat higher price than inspected milk.

Inspected milk is supplied by L. L. Campbell & Brother, 2288 Broadway; Locust Farms Company, 812 Sixth avenue; Meadow Brook Dairy Co., 984 Fulton street, Brooklyn.

Certified milk is supplied by Briarcliff Farms, 573 Madison avenue; Brookside Dairy Farm, Newburg, N. Y.; Hyde Park Milk Co., 587 Madison avenue; Locust Farms Milk Co., 812 Sixth avenue; Meadow Brook Dairy Co., 984 Fulton street, Brooklyn; Sheffield Farms (Slawson, Decker & Co.), Offices of Sheffield Farms; Slawson Brothers and T. W. Decker & Sons; Sugar Loaf Dairy Co., 530 West Twenty-second street; Thorndale Farms Co., 901 Sixth avenue.

## PHILADELPHIA.

**The Phipps Institute and Its Progress.**—The Phipps Institute was established by Mr. Phipps for the Study, Treatment and Prevention of Tuberculosis. Temporary quarters have been taken in a large building well adapted to hospital purposes and near the overcrowded tenement district. The dispensary was opened on Feb. 1, 1903. Within the past month three wards (two for men and one for women) of 16 beds each have been opened for the care of cases in the last stages of the disease. There is no restriction to admission with the exception of a certificate, signed by a member of the applicant's family permitting an autopsy in case of death. As the Institute has for one of its principal objects the *study* of tuberculosis, this is a matter of importance. In but very few instances has this permission been refused.

An emergency ward of four beds has also been provided for those of the dispensary cases suffering from hemorrhages or pleural effusions needing immediate attention. In addition to the three large wards there are ample facilities for the dispensaries, laboratory and post-mortem room.

To date there have been treated in the dispensary 1,167 cases; of this number at least 200 are non-tuberculous. Many of them coming to the institution for an opinion. It is surprising the widespread interest that is being displayed as to the danger of the disease. A complete history and physical examination is made of each case and exact instructions given as to how they shall take care of themselves and avoid transmitting the disease to others. Each case is provided with a paper spit-box, paper napkins and a paper bag for disposing of the soiled napkins. The bag and its contents are destroyed by fire each day. The advantages of sleeping in a well-aired room, keeping in the open air during the day and avoiding exercise are also explained.

The city has been divided into districts for the distribution of milk, which is given free to those unable to pay. This practically includes every one with the exception of those living in parts of the city inaccessible to the milk man. It might be added that no case in a position to pay a reasonable fee to a physician is treated. Information on this point is obtained from the applicant: (1) wages, if working; (2) sick benefits, and (3) expenses for living. It is a simple solution of the dispensary abuses and thus far seems most successful.

Following the scheme devised by Calmette, of Lille, a large map of the city has been provided and by means of pins with colored heads the situation of each case of tuberculosis is indicated. The different colors indicate the amount of milk (1, 2, 3, or 4 quarts) received; also whether the milk has been stopped or the case receives no aid. One of the great difficulties has been to keep a proper watch over the cases and see whether the instructions were carried out. This has been overcome by the appointment of inspectors whose duty it is to visit the houses from time to time and see that the applicants live up to the rules. It is the intention to appoint as inspectors cured or arrested cases from the Whitehaven Sanatorium. This will provide them with employment and having been thoroughly schooled in the treatment, make them competent judges. Of course it is entirely too early to form any conclusions but it can be definitely stated that a large proportion of the cases have shown a slight but consistent gain in weight. The milk which is the best quality obtainable may have some bearing on the question of weight.

**State Board of Medical Examiners.**—The midsummer meeting of the Pennsylvania State Board of Medical Examiners was held during the week beginning June 23. In Philadelphia, 246 candidates were examined and 145 in Pittsburg. President Beates stated that the standard had been considerably raised from that of previous years.

**Improvement Needed at Municipal Hospital.**—As a result of an inspection of the Municipal Hospital, Director Martin has stated that the conditions there are not what persons who are forced to go to the institution should rightly expect. It is stated that more rigid attention should be given to the disinfection of nurses and attendants who are constantly leaving and entering the hospital. The arrangements for the disposal of infected material and refuse are inadequate. A crematory should be erected on the ground in order that this material can be destroyed instead of entering into the sewers. The place is infested with rats, which may be a medium of spreading the diseases under treatment at the hospital.

**Additional Filter Placed in Operation.**—The Upper Roxborough filter plant was placed in operation June 26. With the aid of the Lower Roxborough plant, which was completed several months ago, that portion of the city included in Germantown, Chestnut Hill, Mount Airy, Roxborough, Manayunk and the section lying north of Allegheny avenue, between Broad and Sixth street, will now be supplied with filtered water. The lower plant is now filtering 8,000,000 gallons of water a day. The Upper plant will filter 18,000,000 a day, though at present it is limited to 8,000,000, in order to allow the beds to ripen. The wards now supplied are the Twenty-first, Twenty-second, Thirty-third, and Thirty-seventh. The three latter are at present the center of contagious diseases in the city, and the use of filtered water is expected to bring about a decided change in these conditions.

**Pasteurized Milk Plant to be Installed.**—Nathan Straus, of New York City, has given to Philadelphia a complete Pasteurizing plant, to provide modified milk for the children of the poor of this city. The work is to be carried on by contributions of the people. The old police station at Fifteenth and Filbert streets is being prepared as a site for the plant. The Children's Aid Society has offered a suitable room in its building as a distributing center. The formulæ of milk preparations will be under the supervision of the Philadelphia Pediatric Society.

**Herb Doctor Convicted.**—George P. Hossey, the negro herb doctor who has been on trial for a week, charged with complicity in the murder of William G. Danze, was convicted June 26 of murder in the first degree. The jury was out a little over an hour. Danze died two years ago and the attending physician made out a certificate giving heart disease as the cause of death. The police became suspicious and after a careful investigation Danze's widow and Hossey were arrested. Danze's body was exhumed and arsenic was found in the stomach. It was later discovered that Hossey sold the arsenic to Mrs. Danze, with which, it is alleged, she ended her husband's life. She will be tried in the fall. It is charged that Hossey has been implicated in at least twenty murders.

## CHICAGO.

**Urges Emergency Hospitals.**—County Commissioner Wm. H. Thompson has advocated the erection of three emergency hospitals in the poor districts as adjuncts to the County Hospital, that accidents and emergency cases may receive quicker service. At a meeting of the building committee, he said that many lives might be saved if the patient received care more promptly. Other members of the committee favored such hospitals, if the County Board can get the money with which to build them.

**Plan for a Home for Consumptives.**—Plans were discussed by the county commissioners for the removal

of the consumptives from the county institutions at Dunning, and the building of a new hospital for their care under the most modern methods, at some spot among the highlands in a more remote portion of Cook County. The Commissioners propose to get the $100,000 or more, which the new colony for consumptives would cost, from the proceeds of the $1,250,000 bond issue which was voted by the county at the recent judiciary election.

**Death of Dr. N. H. Henderson.**—Blood poisoning, resulting from an operation for the relief of a dying patient, brought to an end the career of Dr. Nelson H. Henderson, executive head of Lakeside Hospital, of this city. An unnoticeable defect in the rubber gloves used during an operation, and a slight abrasion of the finger, due to a small hangnail, were the contributing causes.

**Preliminary Report of the Milk Committee of the Chicago Medical Society.**—At the last meeting of the Council of the Chicago Medical Society, a committee was appointed to consider the milk supply of the city of Chicago, and was empowered to take such steps as they might consider advisable, with a view of improving the quality of the milk brought into Chicago. It was suggested that the committee act for the Chicago Medical Society in disseminating such information among the profession and the public that might bring about a demand for high grade milk. There are about 628,000 quarts, or 19,600 cans of 8 gallons each of milk supplied to Chicago daily, a per capita quantity of approximately two-thirds pint. To produce this amount of milk, some 50,000 cows are required, on some 5,000 to 6,000 dairy farms. These farms are located in Illinois, Wisconsin, or Michigan, within a radius of 150 miles. Milk as presented to the consumer may be classified, depending on its manner of production, method of handling and quality, as: (*a*) Bulk milk and cream complying with the city ordinance as to quality, equaling three per cent. fat and twelve per cent. total solids for milk, with twelve per cent. fat for cream; (*b*) skimmed milk, marked by a tag bearing the words "skimmed milk," that is attached to the shipping cans and the pouring cans; (*c*) bulk milk that has been bottled in the city; (*d*) bottled milk, the bottling having been done at the stations in the country; (*e*) high-grade milk ("certified"), produced under the most approved dairy methods. Bulk milk and city bottled milk comes from the country on the regular milk trains. It is usually mixed night and morning milk, and leaves the dairy between four and seven o'clock in the morning, and arrives at the various railway milk platforms between 9.30 and 10.30 A.M. The cans are then taken to the city dealer's depot and kept cool until the following morning. Some of it, meantime, is placed in bottles, and is delivered to the consumer twenty-four to thirty-six hours from the time of milking. The milk bottled in the country is about the same age when delivered, but it remains on ice in the country during the day, and is brought into the city during the night. Practically all the bottles are packed in cases that are iced, and they remain iced from the time they are bottled until they reach the consumer. At the present time the chemical quality of the city's milk supply is under control of the Department of Health. By persistent vigilance, a good quality, from the chemical standpoint, is easily maintained. Only one sample is now found below grade to the 10 to 15 found below grade at the beginning of this inspection, ten years ago. Bulk milk will vary most in quality because of irregular mixing. Bottled milk is quite uniform, because a large volume is mixed and filled quickly into bottles. Few persons know of the skimmed milk tag, and many, therefore, get low-grade milk, while the dealer is protected against prosecution. Every housewife has the right to see if there is a tag on the can or not. Today, coloring matters or preservatives rarely are found in the milk. What is especially lacking is sanitary control of the dairy, and this is very difficult, if not impossible, in certain directions. We can only force the farmer to change his uncleanly methods by a slow, laborious education of the public to purchase only such milk as has been obtained under the most approved sanitary methods. The bacteriology of milk is the index of its sanitary condition. The bacteria commonly present are derived in small number from the cow, and in great numbers from extraneous sources. Bulk milk and milk bottled in the city contain the largest number of bacteria, while "certified" milk contains the least number. The number of bacteria in milk can be kept to the minimum by clean milking, quickly cooling, and maintaining a low temperature until consumed. The dairy men are directly responsible for dirty milk. The conditions under which milk is placed in the first few hours after it is drawn determine whether it will be pure or not. During the summer months it is most difficult to maintain the necessary low temperature. The average farmer has no ice, and the ordinary milk train is not a refrigerator car. Bulk milk is presented to the consumer usually just before it sours. Such milk, when bottled in the city, gives a false security, as the consumer believes it has been bottled in the country. Milk produced under fair conditions, bottled and iced in the country, and transported in refrigerator cars, as most bottled in the country milk is, makes a good supply for general use. It is preserved from dirt, it is manipulated less, and cooled at a time when the cooling has the greatest value.

For infant feeding and for the sick, the highest quality of milk should be obtained. Certified milk is produced in a small way only because the demand for it is not large, and did the profession take the interest in the subject that they should, there would be such an increased demand for pure milk that would encourage its more general production. In the feeding of babies, no compromise in the quality of milk can be tolerated. It must be the best milk that we give to the babies, if we would reduce the enormous infant morbidity and mortality that prevail in urban centers.

**Instructions for the Home Care of Milk.**—No milk should be accepted unless bottled and sealed, and delivered from wagons with coolers. The bottle should be taken from the hand of the deliverer (not be left to stand in doorways and halls) and placed immediately upon ice. In the absence of ice, the cold bottle should be wrapped loosely in paper, old newspapers, and kept in the coolest corner. Never put the cold bottle under the faucet, as ample paper wrapping will, if dry, keep out the heat for many hours. Never remove more milk or cream from the bottle than is needed for immediate use, replacing the cover at once. The cover should be handled with a clean fork. If cream is needed, remove carefully by pouring from the top layer. If whole milk, shake the bottle before unsealing. If properly stoppered, it can be inverted repeatedly till thoroughly mixed. When small quantities of milk or cream are needed at short intervals, it is better to order two or more small bottles than one large one, allowing the reserve supply to stand wrapped, sealed and undisturbed. It should be borne in mind that every contact of the milk with cups, spoons, feeders, or even the air, increases the danger of contamination by germs, from which no household is free. Keeping the milk cold is the best means of retarding chemic and putrefactive changes from germs already in the milk. Never pour milk back into the bottle. Flies are the most industrious infection carriers, so that the exposed rim of

the bottle, the stopper and all cups and spoons must be carefully protected from these pests. Visible dirt rarely poisons. It is the unseen germs of disease that may be destroyed only by the free use of soap and frequent boiling of all kitchen and table utensils. Under some conditions milk may be scalded (Pasteurized), or boiled (sterilized), to destroy the germs it contains, and this may be advisable when the milk supply is not above suspicion, but it should be remembered that boiling impairs the food value and also renders the milk less digestible. It does not rejuvenate old milk, but merely makes it "keep" better by destroying ferments which cause putrefactive changes. The committee would suggest that every member of the Chicago Medical Society investigate the milk supply of his patients. No bulk milk or milk bottled in the city should be used under any circumstances. Milk bottled in the country, cooled and kept on ice, can be obtained from a number of milk dealers, and should be the only milk used for general consumption. Certified milk only should be used in the artificial feeding of infants. The committee would also suggest that a permanent milk commission should be organized by the Society to undertake a pure milk crusade, and certify to the grading of all milks delivered in Chicago.

**Endow Medical Paper.**—The *Journal of Infectious Diseases*, a new magazine to be established at the University of Chicago, has been endowed by Mr. and Mrs. Arnold F. McCormick, the parents of "Little Jack," John D. Rockefeller's favorite grandson, whose death from scarlet fever three years ago inspired the establishment of the Rockefeller Institute for Medical Research. It is believed that the eventual endowment fund will be about $125,000. Dr. Ludvig Hektoen, head of the department of pathology and bacteriology at the university, and Dr. Edwin O. Jordan, associate professor of bacteriology, are to be the editors. The first number will appear from the University of Chicago press on January 1.

## CANADA.

**Ontario Medical Association.**—The twenty-third annual meeting of the Ontario Medical Association was held in Toronto on June 16 to 18, under the Presidency of Dr. J. C. Mitchell of that city; Dr. Harold C. Parsons of the same city performing the duties of secretary. It was a three days' meeting, the first time that the Association had ever held a meeting longer than two days, and the success which attended the venture was more than satisfactory to the officers in charge. Dr. J. H. Musser, of Philadelphia, was present and delivered a highly interesting address on the treatment of pneumonia. Dr. Thomas S. Cullen, of Baltimore, contributed a very able paper on the uterine myomata and their treatment. On the morning of the third day there was held a discussion on arteriosclerosis, which was opened by Dr. H. B. Anderson, of Toronto, with a paper on the etiology and pathology of this condition. This was followed by a paper on the cardiac aspect, by Dr. J. W. G. McKay, Oshawa, Ont.; Dr. John Caven, Toronto, dealt with the renal aspect and Dr. Hugh McCallum, London, Ont., with the cerebral aspect. Dr. J. C. Connell, Kingston, contributed to the ophthalmic lesions, while Dr. John L. Davison, Toronto, contributed a paper on therapeutics. The following officers were elected: President, Dr. J. F. W. Ross, Toronto; Secretary, Dr. Charles P. Lusk, Toronto; Treasurer, Dr. Andrew R. Gordon, Toronto.

**Amalgamation of Trinity and Toronto.**—Matters have progressed to a very favorable degree as regards the amalgamation of these two medical schools. A joint agreement has been reached by the faculties of the two universities, which, it is understood, has been signed by the representatives of both faculties, agreeing to amalgamate, and it now remains for Trinity University at an early meeting of that corporation to consider the terms of federation of the two universities and thus wind up the proceedings for one large medical faculty in connection with the provincial university, the University of Toronto. As Toronto Medical Faculty has a student body of 400 and Trinity Medical College one of about 250, the combined forces will make a very large medical school for this city.

**Chief Coroner for Toronto.**—The Ontario Government, during the session of the Legislature just closed, has created in Toronto the position of Chief Coroner and has appointed to the position Dr. Arthur Jukes Johnson, the well-known medicolegal expert. Now, when any medicolegal case is referred to any of the associate coroners, he will immediately report to Dr. Johnson, who shall determine whether or not any inquiry shall be made and will direct what coroner shall have charge of same. This will do away with the wire-pulling which has been indulged in in the past in connection with coroner's inquests in Toronto. The office carries with it an honorarium of $1,500.

## GENERAL.

**Appointment of Dr. Horsley.**—Dr. J. Shelton Horsley, of El Paso, Texas, has accepted the Chair of Principles of Surgery at the Medical College of Virginia, Richmond, Virginia. He has also been elected to one of the positions of attending surgeon to the Memorial Hospital.

**Honor Men at Yale Medical School.**—The anniversary exercises of Yale Medical School were held in the College Street Hall on June 23. The address was by Prof. Henry Mills Hurd, Superintendent of the Johns Hopkins Hospital, Baltimore, on "The Duty and Responsibility of the University in Medical Education." Honors to members of the Medical School graduating class were announced as follows: Degree of Doctor of Medicine, Cum Laude: Charles E. Farr, Athol, Mass.; Albert H. Garvin, Wethersfield, Conn.; Herbert C. Gibner, Bridgeport, Conn., and John E. Lane, Hadley, Mass.

The Campbell Gold Medal for highest rank in the examinations of the course was awarded to Herbert C. Gibner, Bridgeport. The Keese Prize for the most meritorious theses was won by John H. Bailey, of New Haven.

**Yellow Fever in Mexican Ports.**—The sanitary authorities are taking stringent measures to stamp out yellow fever, which exists in nearly all the Gulf ports. Progreso and Merida are the worst affected, but Tampico has an epidemic which is causing anxiety there. Several unsanitary houses have been burned. The bodies of three victims, who tried to escape being sent to the Lazaretto, were found on the outskirts of Tampico yesterday.

**Obituary.**—Dr. F. J. E. Rohmer, one of the best known retired physicians of the South, died at Mobile last Tuesday, aged ninety-one years. He was born in Alsace and was one of the founders of the Charity Hospital in New Orleans.

CLINICAL AND EXPERIMENTAL OBSERVATIONS UPON GENERAL PARALYSIS—TWO MYOMATA UTERI WEIGHING NINE POUNDS—OVARIAN PAPILLOMATA.

Dr. Lewis C. Bruce, at a meeting of the Ophthalmological Society, held May 8, 1903, read a paper entitled "Clinical and Experimental Observations upon General

Paralysis." He said that in his previous communication to the Society, his conclusions were (1) that general paralysis was a disease directly due to poisoning by the toxins of bacteria, the point of attack of which was through the gastric and intestinal mucous membrane; (2) that the poisoning was probably a mixed one, but the *Bacillus coli communis* was apparently one of the noxious organisms; and (3) that the result of treatment by means of serum taken from cases of general paralysis in a condition of remission and injected subcutaneously into early progressive cases pointed to the fact that some form of serum treatment was the proper treatment for this as yet incurable disease. Further observations had led him to modify the second conclusion, that the *Bacillus coli communis* was a cause of the disease. He now believed that the *Bacillus coli* infection was a secondary one. In the Perth District Asylum recent acute cases of general paralysis were rarely admitted, and so the material for observation was therefore limited. Since the commencement of these observations, Dr. Bruce has treated in all eight general paralytics with serum derived from general paralysis in a state of remission. Three of these patients had made apparently complete recoveries. The patient in Case I had been discharged for three years and earned his livelihood as a saddler; the patient in Case II had been discharged for eighteen months and was working in the Post Office; and the patient in Case III had been discharged for nine months and worked as a dyer. Of the remaining five patients, one was relieved and had shown no progressive symptoms for four years. The remaining four were not improved. The leucocytes were regularly examined in two of the patients who recovered and in all the patients who did not improve. The only change noted was a continuous hyperleucocytosis during the period when the serum was being administered subcutaneously in 2 cm. doses daily. In the patients who recovered the leucocytosis fell to below 10,000 per cubic millimeter of blood and the percentage of polymorphonuclear cells was generally below 50. As according to his previous observations the blood of 70 per cent. of general paralytic patients contained an antibody which agglutinated the *Bacillus coli communis* in low dilutions of 1 in 10, he treated two cases with antibacillus coli serum. Neither patient benefited by the treatment. The leucocytosis induced by the subcutaneous injection of antibacillus coli serum was often very high, running to 40,000 per cubic millimeter of blood. Dr. Bruce next investigated the leucocyte changes which occurred in the various stages of the disease. In his first series of observations, he had already recorded that in patients suffering from general paralysis there was a recurrent hyperleucocytosis. In a second series of observations made in six cases the fact of a recurrent leucocytosis was confirmed. Stained films showed that in the first stage of the disease the polymorphonuclear leucocytes were generally present in a percentage of 70 or 80. As the disease advanced these cells diminished in number until in the third stage of the disease they might fall as low as 40 per cent. As the polymorphonuclear cells decreased the leucocytes increased. As eosinophilia was invariably present at some time during the course of the disease and varied from 15 to 5 per cent. of the total number of leucocytes. This eosinophilia was a sign that the disease was active; it was not present in patients who had passed into a definite remission or who had recovered. It was a fact that the course of general paralysis was often temporarily arrested if the patient suffered from some intercurrent inflammatory condition such as erysipelas. To ascertain if this arrest of the disease were due to the leucocytosis induced by the inflammation or to the specific antibodies formed in the blood and tissues, Dr. Bruce made the following observations. Three cases of general paralysis, all with acute symptoms, were treated with small doses of *Streptococcus pyogenes* toxin. The organism was grown on nutrient broth for a week at a temperature of 37° C. The culture was then killed by heat. This was then tested on rabbits to ascertain its virulence. Each patient then received half cubic centimetre doses of the fluid subcutaneously. Case I, a male, showed no reaction in temperature, pulse or leucocytosis and there was no mental benefit. Cases II and III both gave a mild febrile reaction (99° and 99.8° F., respectively). The pulse in both rose to 100; slight leucocytosis was present (14,000 and 15,000 per cubic millimeter). The polymorphonuclear cells rose above 80 per cent. and the eosinophiles fell to one and two per cent. The most marked result, however, was the mental effect. Both patients became quiet and sensible recognized that they were ill, and submitted to treatment. The effect of the first injection passed off in a week, when it was noted that the percentage of eosinophiles was again increasing in the blood. A second and third injection gave exactly the same results and then the patients evidently became immune, as further treatment yielded no results. After a due interval the toxins of the staphylococcus aureus prepared in the same way were injected, but the subsequent reaction was feeble and gave no definite results. The fact that in Case I, where there was no hyperleucocytosis there was no beneficial action, and that in Cases II and III with a hyperleucocytosis with high polymorphonuclear percentage, there was distinct benefit, would seem to indicate that the increased polymorphonuclear leucocytosis was the active agent in assisting recovery. The fact of the rapid reaction to the toxins injected and the immunity quickly produced, as well as the failure in reaction of the *Staphylococccus aureus* would point to the fact that the toxins of the streptococcus had produced some antibody in the blood and tissues which temporarily raised the resisting power of the patients. To ascertain if the increased leucocytosis alone were capable of arresting the disease, Dr. Bruce took Case I of the previous series, in which the patient had not benefited by serum treatment and observed the leucocytosis, temperature and pulse for several days. Two cubic centimeters of terebene were then introduced subcutaneously but with hardly any reaction and without benefit to her mental or physical condition. In the case of a male patient the reaction was marked; the leucocytes went up to 29,000 per cubic millimeter of blood; the polymorphonuclear cells were 80 per cent. There was great physical and mental benefit. In two months he was discharged to his friends. Two cases were treated with antistreptococcic injections of 2 cm. daily for over a month, and both benefited temporarily but relapsed on discontinuance of the treatment. Dr. Bruce thought that the benefit was largely due to the leucocytosis induced. The results of these observations were, he thought, evidence against the theory that general paralysis was a disease due primarily to the breaking down of the brain neurons as the result of syphilitic poisoning, and they supported the more recent view that the disease was due to the direct action of bacterial toxin which, when temporarily overpowered, allow nature to put into force the constant attempts at recovery which were so marked a feature of the disease. Syphilis, plumbism or great mental and physical strain were undoubtedly the predisposing factors, but without the direct bacterial attack there would be no such disease as general paralysis.

Dr. SMYLY, at the Royal Academy of Medicine in Ireland, Section of Obstetrics, April 24, 1903, showed the following specimens: (1) Two myomatous uteri weighing 9 pounds. Ovarian Papillomata. The patient was first seen on Oct. 18, 1902. The tumors, which were confounded with the uterus, on bimanual examination, were

supposed to be myomata. When seen on April 28 the abdomen was very much distended with ascitic fluid and the patient was suffering intense pain. Abdominal celiotomy was performed Oct. 31. The abdominal peritoneum was studded with secondary growths and the omentum was a mass of disease. The two cystic ovaries, which were universally adherent were removed with much difficulty, and also the omentum. The patient recovered. (2) The patient from whom the specimen was removed was first seen in February, 1901. Though she had long passed the menopause a sanguineous discharge from the uterus had been going on more or less for two months. Curetting was advised, but was declined, and she was not seen again until six weeks previously, when a fungous growth was observed to be protruding from the os uteri. Vaginal hysterectomy was performed. The operation was a difficult one owing to the friability of the uterus, but it was successfully carried out and the patient made a good recovery. It was remarkable that an operation was still possible two years after the probable commencement of the disease. (3) This patient suffered intense distress from pelvic pressure, and, the uterus being found enlarged and retroverted, the symptoms were attributed to the displacement. Abdominal suspension of the uterus by Kelly's method was performed, but owing to the obstruction of the bowel, the abdomen had to be reopened, and the cause of the obstruction was found to be an adhesion of the rectum to the cervix, which it had been found impossible to separate at the original operation; the uterus was therefore allowed to return to its former position and the abdomen was closed. Her sufferings were so great that she was obliged to relinquish her employment, and when the removal of the uterus was suggested she readily consented to have the operation performed. About a fortnight subsequently Dr. Smyly performed a supravaginal amputation and the patient made a good convalescence.

## SOCIETY PROCEEDINGS.

### NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

*Meeting of April 17, 1903.*

T. Halsted Myers, M.D., in the Chair.

**Septic Joint Disturbance?**—Dr. Ely presented a young man with peculiar hip symptoms for diagnosis. E. P., eighteen years of age, jeweler. No history of tuberculous or of venereal diseases. About three years ago had malarial fever, which lasted one week and disappeared upon the exhibition of quinine. No history of infantile disease or of pneumonia. Two years ago, while in swimming, felt sudden pain in right knee. About two weeks afterward began to walk lame, and has been lame ever since. Pain grows better and worse, being especially severe after a hard day's work. Does not bother him at night. Eats well and sleeps well. Has also had pain in left shoulder for eighteen months. Only one centimeter atrophy of thigh. The limb is in flexion of 150 degrees, and in abduction and external rotation. Limitation of motion in all directions, and marked muscular spasm. Actual shortening of three centimeters, and apparent lengthening of 2½ inches. The left arm is slightly atrophied, and motion in left shoulder joint is restricted. The X-ray of hip shows nothing.

Dr. Dowd said he thought the case suggested septic joint disturbance, if there are septic conditions of a very mild grade, which affect the joints, causing anchylosis.

Dr. Townsend said that at the Johns Hopkins Hospital, a new method of employing tuberculin was used for ascertaining positively whether a condition was due to tuberculosis or not. The results had proved successful in over 90 per cent. of the cases. He considered this case one of rheumatoid arthritis.

Dr. Northrup said that he made 65 injections at the Presbyterian Hospital in connection with pulmonary lesions. With adults the results were good, and they were published. In the children's wards, he got no reliable results at all. Could not tell whether the reactions were caused by constipation or tuberculosis.

Dr. Myers said that in St. Luke's Hospital he had used tuberculin for diagnosis in children, and had obtained typical reactions where tuberculosis existed. He had found no reaction in rheumatic cases, or in one case of hysterical joint, but had several times obtained the reaction in cases which seemed to be specific. Possibly these were cases of mixed infection. Dr. Myers considered Dr. Ely's case rheumatic rather than tuberculous, neither the glands nor spleen were enlarged.

Dr. Ely said, in closing the discussion, that the case had been a puzzle to him. The patient had been in plaster. He said it was a question now what to do with him.

Dr. Dowd presented the following cases:

**Deformity of the Finger.**—*Case I.*—Deformity of finger following injury received when a small child, resulting in cicatrice which bound the finger down. Skin grafting, as advocated by Wolf in 1875 was employed, and lengthening of tendon as advocated by Dr. Hibbs. The graft was taken from the girl's thigh, the entire thickness of the skin. The finger is nearly straight, which illustrated the fact that a joint can be held an indefinite length of time in a flexed position without becoming anchylosed in that position.

**Paralysis of the Tibialis.**—*Case II.*—Paralysis of the tibialis anticus muscle. Patient came to hospital eighteen months ago. At that time had marked valgus. The tendon of the tibialis anticus was split; part of it was left attached to its own muscle, the other part was brought across and fastened to the extensor tendons. A brace was worn for a time. Patient has now a good gait, and walks almost squarely.

**Tendon Transplantation.**—Dr. Dowd presented another case of tendon transplantation. Patient had a varus due to paralysis of the peroneal muscles. The tibialis anticus was split; the lower end was brought around and attached to the peroneus longus. When the patient raises his foot the new tendon may be seen. The varus is pretty thoroughly corrected.

Dr. Townsend said he had been impressed by the fact that good results were not always noticeable, in these cases of tendon transplantation, at first, but were observed later on which good results were largely due to subsequent treatment. He thought this quite as important as the operation. Patients could not be operated on and turned loose, as the tibialis anticus could not be expected to support the foot entirely.

**Syphilitic Osteitis.**—Dr. Townsend presented a case of syphilitic osteitis of spine and hip. This girl was born in Ireland. Had ulcer on the leg when about six years of age, which was healed by means of some form of ointment used. After that disappeared, the deformity of the spine, which he exhibited, appeared. Two years ago, when she came to the hospital, she had two ulcers on the left leg. They were of the type described as characteristic of syphilis—round, punched out, hard, large, and discharging offensive pus. Family history entirely negative, nothing to indicate disease in father, mother or other children. He did not give much thought to ulcers on account of condition of left hip. The hip presented symptoms of hip-joint disease,

flexion, abduction, tenderness, sensitiveness, very little motion. She was put on iodide of potassium and mercury later, and ulcers healed. Brace was applied, and gait now shows one hip is as good as the other.

He thought that few cases of hip-joint disease could be ascribed to syphilis, but in his case the symptoms which were apparently due to that disease, cleared up on administration of remedies usually given for it. He thought the condition might be due to a neurosis.

Dr. H. L. Taylor said that he had observed that when cases cleared up on mercury, the conditions might usually be ascribed to syphilis. He thought that even if syphilis were present, however, there might be other lesions, not of such a nature. He had watched Dr. Townsend's case, however, and thought that the hip, skin lesions and spine were of syphilitic origin.

Dr. Nathan said that he had known syphilitic joint lesions to get well without treatment, and he had been treating a case of double tuberculous hip disease, in which the child walked about in three weeks after using the iodides.

**Typhoid Spine.**—Dr. Hibbs presented a case of typhoid spine. Boy, age eighteen years. On August 12 developed typhoid fever. Got up from bed September 23, and felt well until November 4. Then in the right lumbar region had a feeling of soreness. The pain increased in severity, extended to left lumbar region and also over the spinous processes. He remained in bed seven weeks. The pain extended to both legs, but was not so severe as in the back. On the night of November 4 he had a chill, followed by fever and delirium. There was no delirium the next morning, and he did not notice any fever. December 12 he got up from bed with some pain; he could not stand alone, and had lost considerable weight and he noticed that the spine was curved, the convexity being to the right, extending from ninth dorsal to last lumbar vertebra. There was marked rigidity, sharp spasm and pain upon pressure. Brace applied on December 24. He visited the hospital January 9; the lateral curve was not so pronounced; there was less pain, which was limited to the left side and he walked more erect. On January 23, when next seen, there was less lateral deviation of spine, though there was still pain on left side. February 6 the spine was straight, and general condition much improved. At no time was there any interference with control of bladder or rectum. Though at his first visit to the hospital the deep reflexes of the knee were exaggerated, now they are normal.

**Diabetes Insipidus, Arthritis of Knee.**—Dr. Hibbs presented a second case for diagnosis.—Girl, age 8 years. Admitted to hospital March 10, 1903. No family history of tuberculosis or syphilis. The child has had measles, otherwise has always been healthy. The patient suffered two years ago from some vague gastric disturbance after which the left knee became swollen, accompanied by loss of function and by pain in the knee. The swelling persisted and other joints became enlarged and temporarily painful and sensitive. The mother is not able to give any more details of the history. The child was found to be fairly well developed and apparently anemic. Central incisors notched slightly but corresponding in no way to the Hutchinson type. Chest, negative, except for a soft systolic murmur heard best in the third interspace on the left side and apparently hemic in character. Abdomen, superficial veins rather well outlined. Patient is capable of distending the anterior abdominal walls to a remarkable extent, so that the more movable viscera are apparently displaced downward, the liver and spleen becoming easily palpable. She is likewise capable of throwing the belly walls into the scaphoid position. If allowed to do so, she will permit urine to collect in the bladder in such amount as to distend this viscus above the umbilicus, after which she will pass about 26 to 30 ounces of urine. She is thirsty and will drink inordinately if permitted to do so, even resorting to the water in which she is bathed. Her appetite is not particularly good. The blood examination reveals a secondary anemia of the chlorotic type. Temperature, pulse and respiration entirely normal. Urine, daily amount, between 95 and 100 ounces; very pale; faintly acid; sp. gr. 1.001; faint trace of albumin; no sugar; numerous pus cells; large numbers of desquamated epithelium—round and squamous; no casts; few urates. There was found to be thickening of the synovial membrane and effusion in left knee-joint, also involvement of the joint of one finger, and phalanx of another. The arc of motion was not limited.

**Hypertrophy of Fringes of Synovial Membrane.**—Another case presented by Dr. Hibbs. Girl, age eleven years. Past and family history unknown. Patient comes to hospital (March 6, 1903) stating that, for six months past, she has been suffering pain in both knees, affecting more particularly the left, and coming on after exertion. She states that she is able to walk 15 or 20 blocks without inconvenience, but that any greater walk results in severe pain in the knees. She has noted that, while skating, her leg has become suddenly stiff as if held by a cord. During this period the leg is slightly flexed on the thigh. After a few moments' rest the limb resumes its former posture. There is no limitation of motion in either joint. On examining the joint, one can feel something like rice bodies, which are painful on pressure. An apparatus has been applied, limiting motion in extremes of both flexion and extension, with lateral support.

**Internal Derangement of the Knee-Joints.**—Also introduced by Dr. Hibbs. Came to Orthopedic Dispensary four days ago. His mother said that for the past three weeks the child had been limping occasionally, and complaining of pain in the knees. Found in each knee a small piece of movable cartilage, which is assumed to be the cause of the difficulty. A loose cartilage was also found over the tip of the external malleolus of ankle, and over the tip of the elbow. They are new growths, or have been chipped off.

**Extreme Rachitic Deformities.**—Dr. Myers presented this case. Colored child now four years old. Has never walked erect. Lies in bed always. Progression is peculiarly apelike; child squats on its haunches and then advances on all fours, the thumbs being turned backward. Feet are in marked valgus; anterior curvatures of tibiæ and femora; coxa vara; prominent abdomen; thorax narrow and horizontal in curvature of ribs, which interferes with action of heart and lungs, rachitic rosary, curvatures of clavicle, cubitus varus, enlarged radial and tibial epiphyses, craneotabes. Previous history unknown. The case was presented especially on account of the extreme muscular weakness, persisting so long, and after most of the sensitiveness has disappeared.

DISCUSSION OF DR. HIBBS' CASES.

**Diabetes Insipidus.**—*Case II.*—Dr. Northrup said that in regard to the fusiform formation of the shaft of the bones of the fingers, it was almost impossible to tell, by looking at the fingers, whether the cause was osteoperiostitis due to syphilitic or tuberculous processes. Almost all fusiform shafts turned out, on autopsy, to be tuberculous; simply from morphology it would be impossible to determine. He thought retroperitoneal, tuberculous nodes, could account for the abdominal appearances.

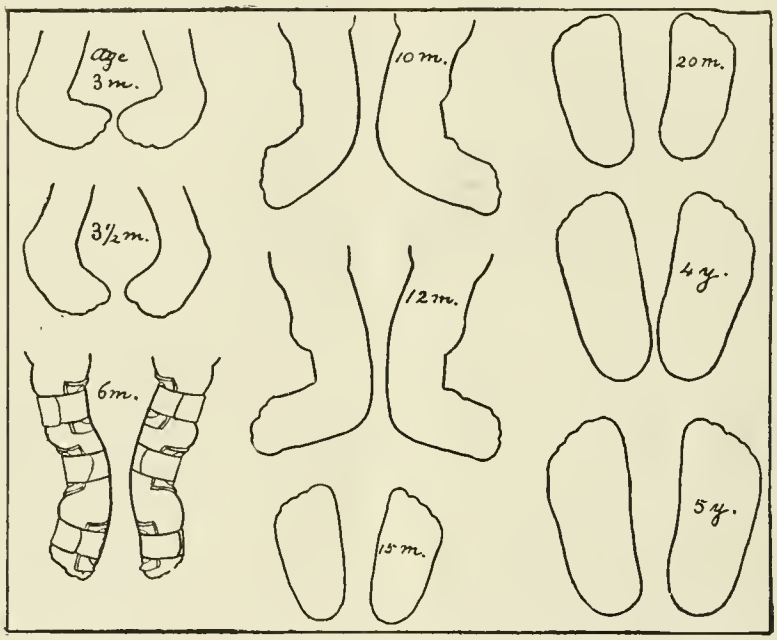
Dr. Freeman thought that tuberculosis would account for almost all symptoms shown by the child. The

joints of the fingers showed tuberculous disease; it has peritonitis and tuberculous pancreatitis. The same changes might be due to syphilis. He thought children seemed to have tuberculosis generalized.

Dr. V. P. Gibney said that he had heard that tuberculosis in children was generalized, but he thought the disease would not go on to tuberculous pancreatitis and involve the mesentery glands without also affecting the brain of the child. The tendency in these cases was rather to develop meningitis. Dr. Taylor said the case did not impress him as tuberculous. He thought a number of conditions were against that diagnosis—the joints showed that they contained fluid, but did not show much of anything else. The bones did not seem to him to be enlarged. He thought chronic white swelling had a distinct physiognomy of its own which this case lacked. He thought it true that fusiform swellings of the phalanges were in 99 cases out of 100 tuberculous, but this case did not show the ordinary features of such swellings. He thought syphilis would account after he had taken violent exercise—long bicycle rides, etc. The disease probably existed before, but was aggravated by the exercise. This boy does not seem to be particularly neurotic. Dr. Ely said he had seen a case of typhoid spine a short time ago, with osteitis of the vertebræ, with marked swelling in back, extreme sensitiveness, muscular spasm and limitation of motion.

**Congenital Dislocation of Left Hip, and Hip-disease in Right Hip.**—Dr. Napier presented a case which he showed for its unusual condition, and also to get the opinion of the section of the feasibility of reducing the congenital dislocation of one hip while there was tubercular disease in the other. Six years ago, operation had been advised for the dislocation, but refused. The child was not seen again until about 2½ years ago, when the diagnosis of tuberculous hip disease was made. This is still in active stage.

Dr. Lorenz saw the case at the King's County Hospital, and suggested the advisability of reducing the dislocation, putting it up in the usual position, and then



The figures show the increase in the size of a child's foot by natural growth, of which advantage may well be taken in the correction of talipes equinovarus.

for the fluid in the abdomen. The cases of floating cartilages, and movable bodies in several joints, he thought interesting and rare. He said he thought the case showing loud crepitation in the knees on motion was one of hypertrophied synovial fringes, rare in children, not so in adults. Goldthwaite has given the results of his study of these cases, with symptoms—sometimes intermittent, sometimes continuous, sometimes mild, sometimes very severe. They are called dried joints. These hypertrophied fringes may be felt at location of crepitus; if the joint should be cut down upon they would probably be found.

Dr. Northrup said the thickening was in the shaft, showing it was true thickening of the bone.

Dr. Hibbs said that he had been treating the case with mercury and iodide, as a means of diagnosis. He could not see any improvement. Had then applied apparatus as explained above.

Dr. Ely said that he had been questioning the boy with typhoid spine closely, and found he had had considerable discomfort ever since his attack of typhoid fever, but had not been bothered by great pain until including the right hip in the plaster spica, letting the child walk on the right leg. If the left hip should be abducted, the other is usually adducted, in order to bring the leg down so the patient can walk, and that would not be a good position for hip disease. The child is nine years old.

*Case II.*—This was also presented by Dr. Napier, who at first thought it to be a typical case of posterior curvature with lateral deviation. On examination on table, back was found to be a little stiff, as is often the case in posterior curvature. Slight swelling to the right of the dorsal spine, containing fluid, apparently following a fall he had in playing leap-frog, when he landed on his head. Since the swelling has appeared for the last two or three months, he has moaned at night, tired easily, and for the last month or six weeks has had a little difficulty in walking, and falls frequently. There is increased knee-jerks, and ankle clonus on both sides. At night has pain in dorsal spine. No angular prominences in spine. It is stiff in dorsal region, there is a round kyphosis, hardly more than round shoulders. On account of other symptoms, it

seems to be a case of spinal osteitis. The boy is now having difficulty in holding urine.

**Effect of Growth in a Case of Clubfoot.**—Dr. A. B. Judson.—The chart presents the history of a case of talipes equinovarus. Treatment was begun when the boy was three months old. There had been no previous treatment. The outlines were taken at 3 months, 3½m., 6m., 10m., 12m., 15m., 20m., 4 years and 5 years. The case is not presented for the purpose of illustrating the method pursued, or as an illustration of unusually successful treatment. The patient was before the Section in March, 1901, when the last outline was taken, one year after the restoration of normal shape and ability and the cessation of treatment. Fortunately such results are common, and becoming more common all the time, now that it is recognized that operative and forcible measures are not required in cases of this kind if the surgeon is freed from the necessity of being in a hurry and has the assistance of intelligent attention to the patient at his home. The chart is presented because it shows the increase in size which the foot acquires by its natural growth and brings prominently to view a fact lying at the base of orthopedic practice in general, the fact that our results in prevention and cure are to be sought and found in so managing the case and so equipping the patient that his growth will be the principal curative agent leading to symmetry and ultimate ability, which brings to mind the old saying: "As the twig is bent the tree's inclined," and also the derivation of the word orthopedic, in accordance with which we may say that orthopedic practice leads the deformed child to grow straight. The success in these cases is greater than it appears to be on the surface. Restoration of ability is still more important than restoration of shape, and in this also we are assisted by the patient's growth and development. If the bones are held in normal relation to each other the ligaments and muscles develop, by exercise, normal passive strength and active power with the increasing activity and weight of the patient.

DISCUSSION OF DR. NAPIER'S CASE II.

Dr. V. P. Gibney thought the case one of lateral curvature, primarily tuberculous, with paraplegia. Abscesses came with no angular prominences. May have had Pott's disease before.

**Etiology of Rickets, etc.**—Dr. Freeman made some remarks on this subject. He discussed the causes that had been suggested and the experiments that had been carried out to demonstrate that one or another of these causes was a real factor in the etiology of this disease, and showed that most of these experiments had given negative results. He then related certain observations made in New York by himself and others, on babies living in the tenements and in certain institutions, showing the remarkable frequency of this disease in institution children, even when their surroundings were hygienic and they were fed for the most part on breast milk.

Dr. Northrup said the first thing to do in the study of the cause of rickets was to clear the deck of all old theories which were not of service, and only consider those that were. He had found that babies having best of care in hospitals were as subject to the disease as those brought up in tenement houses.

Dr. V. P. Gibney said he did not know what caused rickets, and was simply there to admire the work of Dr. Freeman in collecting such valuable statistics.

Dr. Taylor admired Dr. Freeman's work, but thought the statistics were taken from far too few cases, and from far too limited a class of infants, to draw any very wide generalization. He thought results must be repeated by different observers for a number of years, before generalization could be made. He had noticed that dirty tenement children were no more subject to rickets than the well-cared-for, and thought the trouble was with the food. He thought sterilized more digestible than raw milk.

Dr. Nathan thought that where infants were nursed by their mothers, rickets were of less frequent occurrence.

## BOOK REVIEWS.

SURGICAL EMERGENCIES. The Surgery of the Head. By BAYARD HOLMES, B.S., M.D., Professor of Surgery in the University of Illinois, Professor of Clinical Surgery in the American Medical Missionary College, Chicago; Attending Surgeon to the Chicago Baptist Hospital. D. Appleton & Co., New York.

ALTHOUGH intracranial neurectomy of the fifth nerve and amputation of the tongue for carcinoma are scarcely to be classed as coming under the head of emergency surgery, still the present volume displays so many excellencies both of matter and arrangement that some trifling inconsistencies may readily be condoned. The preface seems to indicate that this is the first of a series of volumes which are to discuss the regional surgery of the entire body in such a way as to be most useful to the student and general practitioner.

The author has set himself to present the material in the manner most likely to produce a vivid and permanent impression and has succeeded in producing a most readable book, full of interest and profit for readers in every stage of professional evolution. The introduction of numerous histories of more or less dramatic cases is skilfully done so as to add point to the didactic material without impairing its continuity and is a valuable feature from the pedagogic standpoint. The entire domain of cranial and facial surgery, exclusive of the specialties, is covered and excellent advice given for the treatment of the commoner casualties, which are discussed in detail while the more unusual conditions are passed over with a lighter touch. Numerous illustrations and several colored plates adorn the text and help to confirm the favorable impression the volume makes.

VEASEY'S OPHTHALMOLOGY. A Manual of Diseases of the Eye. For Students and General Practitioners. By CLARENCE A. VEASEY, A.M., M.D., Demonstrator of Ophthalmology in Jefferson Medical College, Philadelphia. Lea Brothers & Co., New York and Philadelphia.

THIS is a valuable addition to the list of smaller handbooks on special subjects. A fair working knowledge of the diseases of the eye is as necessary to the general practitioner as the ability to use the stethoscope and we know of no other book which presents the outlines of the subject in so practical a way as this. The task of selection is great in the preparation of such a work and the author has been most successful in keeping his material within the limits of a manual without sacrificing completeness. Much is due to the very happy general arrangement and the systematic and concise way in which each subheading is discussed. The hand of the experienced teacher as well as of the skilful clinician is evident on every page and the result is very near perfection both from the standpoint of the student who seeks clearness and directness of exposition, and of the practitioner who requires a reference book for counsel in every-day work. Unlike many books of this class written mainly as text-books, this is a practical treatise and the department of therapeutics has been accorded

unusual space so that one will never turn to it in vain for hints as to treatment.

The illustrations are excellent and, for the most part, well chosen, though we think that albuminuric retinitis and optic neuritis, being the two conditions which the non-specialist is most likely to desire to recognize in his patients, might have been given a place among the colored plates rather than some of the rarer lesions so figured. The demonstration of tubercles in the choroid also sometimes forms the crucial point of a difficult differential diagnosis and a black and white cut, at least, of the condition should be included.

The American Year Book of Medicine and Surgery. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery. Drawn from Journals, Monographs, and Text-books of the Leading American and Foreign Authors and Investigators. Collected and Arranged with Critical Editorial Comments. Under the General Editorial Charge of George M. Gould, M.D. Surgery. W. B. Saunders & Company, Philadelphia, New York and London.

The present volume of this excellent annual is well up to the high standard of its predecessors and offers a very satisfactory conspectus of surgical progress during the past twelve months. The collaborators have shown nice discrimination in their selection of material and the references bear witness that the most important surgical publications of the old and new worlds have passed under their eyes. The editorial comments for the most part are apt and give an added value to the sections they discuss while the abstracts themselves are models of concise but lucid expression.

Sections of especial importance are those on the surgery of the peritoneum and intestines, including an admirable description of the operation on President McKinley, and those on gynecology and obstetrics which are remarkably comprehensive.

The illustrations accompanying more important articles are reproduced in full; particularly interesting is the series of plates showing the results of Kelly and Brödel's study of the blood supply of the kidney with a view to the technic of nephrotomy. The index is comprehensive and the book is almost a necessity to every one engaged in active work.

Treatise on Diseases of the Eye, Nose, Throat and Ear. For Students and Practitioners. By various authors. Edited by William C. Posey, A.B., M.D., Professor of Ophthalmology in the Philadelphia Polyclinic, and Jonathan Wright, M.D., Surgeon to the Manhattan Eye and Ear Hospital, etc. Lea Brothers & Co., New York and Philadelphia.

This is the best book with which we are acquainted in the English language on the cognate subjects which it treats. Unlike many composite works of similar construction we believe that the editorial supervision of the work under consideration is very well done. The contributors, among whom are such well-known specialists as Alderton, Birkett, Casselberry, Cheatle, C. F. Clark, E. T. Collins, Crockett, Duane, Ellett, Gifford, Goodall, Hopkins, Miller, William C. Posey, Reeve, C. W. Richardson, E. A. Shumway, W. K. Simpson, T. H. Spencer, E. G. Starr, W. N. Suter, S. St. Clair Thompson, C. A. Vesey, J. E. Weeks, C. A. Wood and H. William, such an array of eminent authorities speaks for the scientific character of the book.

Comparisons between the different chapters are invidious and we therefore hesitate to pick out any that commend themselves especially to our praise. In fact all of the articles are of a high order. The illustrations are numerous and well chosen, and taken all in all we know of no work of similar character that fulfils its many useful functions. The new edition by the publishers in two volumes meets the only plausible criticism of the first edition, *i.e.*, its bulkiness.

Transactions of the American Orthopedic Association. Sixteenth Session, Held at Philadelphia, June 5, 6 and 7, 1902. Appendix. The published writings of the present active members. References to orthopedic literature published from May 1, 1900, to July 1, 1902. Volume xv. Published by the Association. Philadelphia.

This collection of papers read at the last session of the American Orthopedic Association contains much that is of interest to the general surgeon and to the family practitioner. Orthopedic surgery, dealing as it does essentially with chronic diseases and stretching its treatment over long periods of time, often demands the co-operation of the family practitioner whose skill is required in the case of intercurrent maladies. General practitioners and surgeons may very properly be expected to add a Year Book of Orthopedics to their libraries and these transactions afford a most satisfactory résumé of recent work in this specialty. Papers of particular interest are those on "Internal Derangements of the Knee-joint," by Peckham; "Congenital Dislocation of the Hip" and "A New Treatment for Fracture of the Neck of the Femur," by Whitman; and a very practical and profusely illustrated article on "Shoe Deformities," by Bradford.

Bacteria in Daily Life. By Mrs. Percy Frankland. Longmans, Green & Co., New York.

Popular treatises on bacteria and on their relationships to processes in the phenomena of every-day life are neither numerous nor well written. The present volume, however, is an exception to this generalization. It is written by one who is thoroughly acquainted with the subject from a standpoint that is distinctly non-medical and in a style which is charming. We can recommend it most highly both to the technical reader and to the physician, particularly as a work that he can recommend to his patients who are interested in bacteriology from the lay standpoint.

Laboratory Exercises in Bacteriology. An Outline of Technical Methods Introductory to the Systematic Study and Identification of Bacteria. Arranged for the Use of Students by Allen J. Smith, M.D., Professor of Pathology in the University of Texas. P. Blakiston's Son & Co., Philadelphia.

Laboratory manuals in bacteriology grow apace, but very few of them take up the study from the standpoint of the present author. His point of view is systematic bacteriology, a standpoint which we feel is absolutely essential in any modern treatise devoted to the subject of the science of these micro-organisms, and we thoroughly believe with the author that the best way to approach the subject of bacteriology, even for the medical student, is to enter through the channel of systematic bacteriology.

Bacteria being plants, their classification should be a purely botanical study. Their later physiological action and the detailed study of pathological forms, which are of so much interest in medicine would best be considered as a by-product of certain phases of these plants. It is only in this manner, we believe, that a comprehensive view of the study of bacteria can be gained and, therefore, the present outline is particularly to be commended.

# THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 83. NEW YORK, SATURDAY, JULY 11, 1903. NO. 2.

## ORIGINAL ARTICLES.

### STOMACH VERTIGO.*

BY CHARLES SUMNER FISCHER, M.D.,
OF NEW YORK.

As the diagnosis of stomach vertigo is uncertain at best, and in view of the fact that the literature upon the subject appears at infrequent intervals, it would seem advisable before entering upon this discussion, to enumerate the principal characteristics of this form of vertigo, as described by Trousseau. According to this authority, they appear to be the following: there is no loss of consciousness and the patient never misunderstands the nature of his hallucinations; great fear attends the attacks; vision may be affected, objects may appear in a variety of colors, or all objects may revolve with excessive rapidity; pressure sensations may exist in the head and this form of vertigo does not occur when the head is lowered. The gastric symptoms described by Trousseau consist of pain in the epigastrium which upon pressure may radiate to the thorax, back, or even the extremities, and burning sensations within the stomach. Constipation exists as a rule, but there may be diarrhea. The attacks occur usually when the stomach is empty and may be relieved by taking food, or they may occur immediately after meals. At times all dyspeptic symptoms are absent.

It has appeared necessary to enumerate these principal features in order to establish some basis for the correct diagnosis of this condition, for it sometimes happens that cases are reported as gastric vertigo which do not give the clinical features of this form. I refer especially to conditions of intense cardiac, pulmonary, and cerebral disturbances, accompanied by vertigo, which occasionally follow attacks of acute indigestion. In such cases, the vertigo is but a part of a severe train of nervous and vasomotor phenomena which may follow indiscretions in diet, but it is not possible to regard the vertigo as the principal feature of these attacks.

The description of the cerebral phenomena given by Trousseau is clear, but the uncertain knowledge and classification of gastric diseases existent at the time did not permit of much specification in this direction, and hence, it has generally been accepted that stomach vertigo is an occasional accompaniment of chronic gastric catarrh, whatever this term might signify. As, however, the classification of chronic gastric diseases has been developed in succeeding years, the possible application of the term chronic gastric catarrh has become more limited and, as a result, attempts have been made from time to time to associate gastric vertigo with the various well-defined pathological conditions revealed by a more scientific study of diseases of the stomach.

A simple classification of chronic gastric diseases for the present purpose would be the following: (1) Disorders of secretion due to inflammatory or non-inflammatory conditions; (2) disorders of motility resulting in atony or dilatation; (3) displacements; (4) simple neuroses. Such a classification would tend to prevent confusion and it remains to be determined whether gastric vertigo can be associated with any one particular class mentioned.

Numerous attempts have been made in this direction. Ewald, Leo, Rosenheim and Fleischer regard vertigo as a possible complication of chronic inflammatory disease of the stomach. Boas, Pick and Herz attribute it to atonic conditions. Fleiner and Hemmeter look upon it as one of the many results of neurotic affections and Hayem and Robin suggest that it may occur in connection with any chronic gastric disease. A further difference of opinion exists as to the relation, if any, which may be present between the vertigo and the acid secretion of the stomach.

In this regard, Ewald and Leo would have it occur most frequently in connection with hypochlorhydria, while Fleiner, Riegel and Hemmeter suggest that hyperchlorhydria is usually found. There are others, among them, Fleischer, Rosenheim, Boas and Hayem who hold that any degree of gastric acidity may be possible during this complication. Various views have also been projected in regard to the frequency of this form of vertigo. Boas, Rosenheim, Hemmeter and Riegel look upon it as a frequent complication, whereas Fleischer and Hayem have rarely observed it. Singer, in an analytical discussion of the cases presented by Trousseau, denies the possibility of vertigo as a direct result of gastric disease and Hayem suggests that in most cases an eye or an ear lesion will be found to exist. Leube declares that vertigo occurs in 17 per cent. of cases of nervous dyspepsia and rarely complicates cases of dilatation.

The mechanism of production of gastric vertigo has been a subject for much speculation and, as Hemmeter suggests, rests entirely upon hypothesis. The older observers regarded it as a reflex phenomenon, but the manner in which such a reflex could be produced was a subject for theory based upon reasoning by analogy from observation of the effect of gastric irritation upon the heart's action and the pulmonary circulation. When Trousseau asserted that this form of vertigo was the result of reflex action through the sympathetic and vagus nerves upon the vasomotor centers, his assumption appears to have

* Read before the New York Academy of Medicine.

been verified by the observations and experiments of Mayer and Pribram upon the effect of gastric reflexes upon the pulmonary circulation. These experiments seem to indicate that irritation of the coats of the stomach may cause constriction of the arterioles in various parts of the body, thus producing increased resistance to and interference with the action of the left ventricle. Barie and Potain suggest, in this connection, that the reflex influence leads to a dilatation of the arterioles and labored right heart action. The same difference of opinion exists as to the condition of the cerebral circulation in cases of gastric vertigo. Trousseau maintained that cerebral congestion was present during such attacks, whereas Leube regards them as a result of cerebral anemia. Reasoning by analogy from Fleiner's observations upon allied conditions, such as hemicrania-gastrica, which according to him may be either sympathico-tonic or angio-paralytic, gastric vertigo might possibly be due to either cerebral congestion or anemia, assuming always that it is a result of vasomotor disturbances.

A further difference of opinion exists as to the routes pursued by these reflexes. Two possibilities appear in this connection. One of them carries the impulse directly from the stomach through the vagus and sympathic nerves to the cerebral centers. Those who accept this explanation, reason by analogy from the experimental studies mentioned above and from such cases as those of Leube in which a simple digital rectal examination or the passage of an ordinary lavage tube caused intense vertigo. I have encountered one such case, myself. It was that of an intensely neurotic woman in whom suggested rectal alimentation had to be abandoned on account of the servere cardiac and vasomotor and cerebral disturbances which would follow immediately upon the introduction of a nutrient enema.

The other theory carries the gastric reflex impulse to the centers of equilibration indirectly through the labyrinth. According to Woakes, the internal ear receives its blood supply from the vertebral artery and its branches, which latter also supply the inferior cervical ganglion. This receives a branch of the pneumogastric nerve and thus offers an explanation of the intimate relation existing between the labyrinth, the heart, and the upper part of the intestinal tract. The direct cause of the vertigo, if this conception is correct, would consequently be some irregularity in the blood supply of the labyrinth. In 1885 Menière accepted the theory of Woakes and attempted to prove by clinical statistics that chronic gastric diseases could cause ringing in the ears and even deafness. Of 24 cases examined, 43 are said to have complained of ringing in one ear, and audition was impaired in 50 per cent. All other theories are based upon these original statements of Woakes and Menière. Fleiner suggests in this connection, that the impulses might be transmitted from the stomach through the pneumogastric nerves to their centers in the medulla. These lie adjacent to those of the acoustic nerves If in neurotic individuals the centers for both these nerves have been irritated for a length of time, an impulse received in one might be transmitted to the other and thus lead to disturbance in labyrinthine pressure resulting in tinnitus aurium and vertigo.

Since the sweeping claims of Bouchard for auto-intoxication as the cause of all nervous phenomena attendant upon chronic gastro-intestinal diseases were first advanced, numerous attempts have been made to directly connect gastric vertigo with this condition. As little actual knowledge exists as to the nature of the toxines producing auto-intoxication, it is difficult to understand why in one case they should produce tetanie, and in another vertigo, except perhaps upon the uncertain basis of individual predisposition. Some assistance to a solution of these problems might be obtained from any definite knowledge which we might possess of the local gastric conditions under which the poisons are produced. Here, however, opinions differ again. Bouveret and Devic isolated their toxines from cases of hyperchlorhydria, whereas Cassalt and Féré extracted the same substances from normal stomachs. On the other hand, Brieger, Fleiner, Bamberger and Albu assert that these toxines can only be obtained from those cases in which fermentation and putrefaction are rendered possible by impaired muscular activity of the stomach. Boas contends that gastric vertigo can only occur in myasthenia gastrica and Pick in an analytical study of some 50 cases, reports an atonic condition in each one. Whatever may be the respective merit of these views, their practical development is more likely to lead to important results, for they have for their object the determination of the pathological conditions in the stomach necessary for the production of such phenomena as do occur in the central nervous system in connection with gastro-intestinal diseases.

That any actual relation exists between abnormal gastric acid secretion and vertigo has never been demonstrated and it appears to have been a matter of chance that some observers have reported hyperchlorhydria and others hypochlorhydria. This is natural when we consider that we may have any degree of acid secretion in connection with most chronic gastric diseases. Chronic gastritis, atony or dilatation, the various neuroses, and the displacements may show increased or diminished acidity, the extent of which will depend upon the duration of the disease and the pathological changes in the mucous membrane. If vertigo is associated with cronic gastritis in its early stages when proliferative changes are taking place in the mucous membrane hyperchlorhydria may be found. If, however, the disease has progressed to the atrophic state, hypochlorhydria will be present. The same rule exists for most of the other diseases, especially so for atonic conditions. The hyperchlorhydria which may occur in the early stages of atony and which is due to the prolonged irritation resulting from food stasis, will in time give way to normal

acidity and finally to subacidity in consequence of exhaustion due to overstimulation. I have seen attacks of vertigo repeated through these stages in the same case. The great fluctuation in the amount of acid secreted at different times in the same individual in the distinctly neurotic affections of the stomach renders the determination of any relation between this function and the vertigo extremely difficult and uncertain, and yet in this class of cases, vertigo occurs most frequently.

I have taken from my records a certain number of cases bearing upon these points. In these cases an exact diagnosis of the gastric conditions was assured by repeated chemical and physical examinations and both the slight and severe forms of vertigo have been included.

Of 50 cases of nervous atonic dyspepsia associated with vertigo, 66 per cent. were subacid and hyperchlorhydria existed in 10 per cent. Of 50 cases of purely nervous dyspepsia associated with vertigo, 42 per cent. were subacid and hyperchlorhydria was found in 17 per cent. Of 50 cases of chronic gastritis associated with vertigo 78 per cent. were subacid and hyperchlorhydria was present in 7 per cent. In 25 cases of dilatation vertigo was present in 7. Of these 4 were subacid. In 25 cases of gastroptosis vertigo was present in 5. Of these 3 were subacid. I have further found that in cases of achylia gastrica and hyperchlorhydria, taken irrespective of the underlying basis, vertigo occurs twice as frequently in the anacid variety as in the hyperacid.

From these figures it might be concluded that some relation did exist between subacid conditions and vertigo. That this is only apparent will appear from the following percentages of acidity taken from the same number and variety of diseases, not associated with vertigo. Among such of nervous atonic character, 33 per cent. were subacid and hyperchlorhydria was found in 11 per cent. Of the purely neurotic cases 39 per cent. were subacid and hyperchlorhydria existed in 20 per cent. Of the chronic gastritis cases 72 per cent. were subacid and 10 per cent. the reverse. Among the dilatation cases subacidity was found in 31 per cent. and hyperchlorhydria in 17 per cent. and of the cases of gastroptosis 60 per cent. were subacid and hyperchlorhydria was present in 10 per cent.

Such figures would seem to indicate that very little difference exists between the percentages of acidity found in the vertiginous and non-vertiginous cases. The excess of subacidity shows itself in both classes and the percentage of hyperchlorhydria is approximately equal in both. Whatever of value these statistics may have they at least demonstrate that very little relation exists between gastric acidity and the vertigo, for it is reasonable to suppose that if this were the case, that abnormal secretion which causes the greatest irritation, would preponderate. On the contrary, we see that the reverse is true. On the other hand, if subacidity were a causative factor in the production of vertigo, we would expect to find the greatest number of such complications among those cases in which subacidity is most prevalent, namely, cases of chronic gastritis. Vertigo is found, however, in only a small percentage of these cases. The greatest variation in gastric acidity exists among the neuroses and vertigo is mostly associated with these cases. It is well known that the abnormal acid secretion in such cases is the result of central nervous influence. This being so, any direct relation between gastric acidity and the vertigo becomes still more improbable, for the same impulse which increases or depresses the secretion is very likely to affect the vertigo through the cerebral centers responsible for this phenomenon. In truth, attacks of vertigo are just as likely to occur during periods of secretory depression as they are during periods of stimulation.

While there appears to be no connection between the vertigo and the various degrees of gastric acidity, it is still possible that an abnormal acid secretion might be the remote cause of the vertigo by inducing certain irritability of the mucous membrane and thus rendering it more impressionable. In this connection, however, it must be remembered that gastric irritability and gastric acidity are not always interchangeable conditions for achylia gastrica may exist for a long time without dyspeptic symptoms. It is further known that the diagnosis of hyperchlorhydria in certain cases is purely a relative one since through Talma we have learned that what is usually considered a normal quantity of free hydrochloric acid may, under certain local conditions of hyperesthesia, be regarded as a true hyperchlorhydria for that particular individual.

The simplest clinical indications of gastric irritability are pain and nausea, and if the latter is accompanied by vomiting, it may be regarded to a certain extent as an index of the reflex possibilities from the stomach. It would be interesting to know in what proportion of cases these two subjective symptoms were pronounced. An examination of the cases with this end in view reveals that in the purely neurotic cases with no atony and with vertigo, no pain whatever was present in 57 per cent., only slight painful sensations existed in 21 per cent., and considerable pain was endured in 22 per cent. In the same class of cases without vertigo the figures were practically the same, namely, 46 per cent. without pain, 28 per cent. with slight pain, and 26 per cent. with excessive pain. Nausea existed in these same cases in somewhat similar proportions. In those with vertigo it was absent in 50 per cent., occasionally present in 35 per cent. and pronounced in 15 per cent. In those without vertigo it was absent in 59 per cent., slight in 27 per cent., and pronounced in 14 per cent. These observations would seem to indicate that very little causative relation exists between gastric irritability and vertigo in the minor inflammatory affections of the stomach. In the inflammatory cases the proportions were practically the same. In the series representing chronic gastritis, with vertigo, pain and nausea were absent in 75 per

cent., while in those without vertigo the same symptoms were absent in 80 per cent., differences which are hardly worth considering.

In estimating the value of these statistics, it should be remembered that clinical statistics bearing upon chronic gastric diseases should always be taken with great reserve for here as no where else does so much depend upon the habits and surroundings of the individuals, so that what might be true for one class of patients under their conditions of life, might not be so for another class with entirely different conditions. Still, allowing for this contingency and taking a broad view of the results, it does appear that no determinable relation exists between gastric acidity, gastric irritability, and vertigo, a conclusion which corresponds with the observation of Trousseau who states that in many of his cases stomach symptoms were entirely absent. This view is further supported by the fact that vertigo is morely likely to be associated with the early stages of chronic gastric diseases than it is with the advanced changes in secretion and motility entailing pronounced suffering.

The frequent association of vertigo and atonic conditions in the stomach has led to the belief expressed in some quarters that this form of vertigo is always due to impaired motility or the fermentation resulting therefrom. There are certain facts to be considered in this connection. That vertigo should be associated most frequently with atony is comprehensible, for atony is probably the most common pathological condition known among chronic gastric diseases. It should further be remembered that most cases of atony have sprung from general neuroses with this result, that the nervous atonic dyspepsia is the most universally distributed. It will often be found, however, upon close examination that the vertiginous attacks antedate the gastric symptoms in these cases. Atony is not a common accompaniment of chronic gastritis, but vertigo does occur in a certain proportion of such cases. The same can be said of gastroptosis, whereas in cases of dilatation due to atony, the gradual transition from one condition to the other, does not result in increase in the frequency of the vertigo.

The impression which is effected upon the central nervous system for the production of gastric vertigo in cases of atony, may be accomplished in two ways. It may be the result of reflex action due to increased intragastric pressure from excessive gas production, or it may be due to auto-intoxication from toxine production. So far as the production of gas is concerned, it was found upon analysis of the cases given above that of the nervous atonic cases only 30 per cent. were afflicted with excessive epigastric pressure, whereas the cases of chronic gastritis gave this symptom in 70 per cent. In order to explain this discrepancy it would be necessary to assume that a combination of moderate gas production and excessive gastric irritability might exist, and thus produce the necessary reflex. When we consider, however, that these cases are usually subacid and that the suffering attendant upon them amounts to discomfort rather than great actual distress, the direct association of the vertigo and gas production becomes still more difficult. It should be remembered in this connection that most chronic dyspeptics are liable to ascribe all their symptoms to the excessive production of gas. In many cases, however, it will be found upon close examination that no reason for such exists and that all the pressure symptoms will disappear upon the administration of some local sedative.

As a certain irritability of the nervous system is necessary for the production of vertigo and as such irritability usually results in the course of chronic gastric diseases, it has been assumed by some authorities that the primary causative factor, under these circumstances, is auto-intoxication, thus offering a second possible explanation for vertigo in atonic conditions of the stomach. It is very probable, however, that other influences, such as malnutrition, are at work here also, for the fermentation resulting from food stasis may not only produce toxines, but in so doing convert a certain portion of the ingested food into products which are devoid of nutritive value. In this way, the general nervous irritability is explained and auto-intoxication stands as the remote cause for any of the nervous phenomena which may occur under these circumstances. Why in the one case the phenomenon should be vertigo, in other tetanie, and so on, can only be explained upon the uncertain basis of individual predisposition, which latter is again determined by the habits, occupation and surroundings of the subject. Hence, given gastric conditions which make auto-intoxication possible, we have in this a plausible but indirect explanation for the slight and momentary attacks of vertigo so common in the course of chronic gastric diseases. Auto-intoxication, however, cannot account for the vertigo in cases where no conditions exist for toxine formation, nor can it account for the sudden and violent form described by Trousseau. In the latter cases, it would be necessary to assume the sudden production and absorption of a large quantity of toxin, which is hardly conceivable without decided gastric symptoms. Where such rapid production does take place the reaction on the part of the nervous system is general and vertigo may or may not be an accompaniment of the complex disturbance. Added to this we have observations that the condition described by Trousseau is uncommon in cases of intense dilatation due to pyloric obstruction and yet these are the most fertile conditions for auto-intoxication.

This difficulty in connecting actual gastric conditions with vertigo is probably the chief reason for the various opinions in regard to the frequency, cause and diagnosis of this phenomenon. The simple association of vertigo with nausea and vomiting is not sufficient for the diagnosis of stomach vertigo, for all forms of vertigo, from whatever source, if persistent enough, will be accompanied by nausea, nor does the fact that

artificially induced vomiting will cut short an attack, render the diagnosis assured. Vomiting is sometimes induced for the purpose of relieving muscular spasm under other circumstances, so that it is reasonable to assume that it would act likewise in conditions of vasomotor spasm. It appears that cases sometimes are reported as gastric vertigo, simply because there happens to be some such association, when in reality, upon close inspection, it will be found that the gastric symptoms represent a result and not a cause. In other and more severe forms of nervous reactions, due to intragastric conditions, the vertigo is but a part of a disturbed whole to which the terms "dyspeptic asthma" or "angina" could be applied with equal felicity.

Such arguments appear to indicate that the determination of the frequency of gastric vertigo must depend largely upon a correct judgment of the factors which constitute this condition. Are we to take as examples only such cases, the type of which has been described by Trousseau, or can we include all cases in which vertigo and certain pathological gastric conditions happen to be associated. In the one case gastric vertigo would be rare, in the other, exceedingly frequent. In order to partially obviate this uncertainty, it would seem desirable to have some classification of the various conditions of association of vertigo and chronic gastric diseases. Such a classification must be imperfect at best for the various types will often run into each other, but even in an imperfect form, it may assist in differential diagnosis.

A classification, which would include the various types, is the following: (1) Cases in which the vertigo is intense and the only prominent nervous symptom. There may or may not be gastric symptoms and there may be no history of dietetic indiscretion. This is the type described by Trousseau; (2) cases in which the vertigo is associated with intense palpitation, precordial fear, dyspnea, and possible syncope following isolated acts of indiscretion in diet; (3) cases in which the vertigo occurs as a momentary sensation in the course of well-defined pathological conditions in the stomach. These types are given in the order of their frequency and the mechanism of production varies according to the one involved.

The first class assumes the existence of a chronic gastric disease with or without dyspeptic symptoms. There need be no act of indiscretion in diet and the discrepancy between the severity of the vertigo and the gastric symptoms is often pronounced. This may be so to such an extent that some authorities have doubted the existence of this type. Trousseau admits that in some of his cases the attacks were produced by regarding a revolving object and that a general tonic treatment was sufficient to reduce their frequency. These attacks occur with great suddenness and at times in individuals in apparent health. In rare instances, they may occur during sleep at night. A prominent feature is the great fear which attends them, an intense impression of impending evil. Beyond slight palpitation there need be no other symptom, and the attacks are usually of short duration. Sometimes they end in a spell of vomiting. They are usually infrequent, but may recur with a certain periodic regularity, one attack predisposing to another. The mechanism of production in these cases can only be a reflex for it scarcely seems possible to assume auto-intoxication as the cause, unless we acknowledge the sudden formation and absorption of a certain quantity and quality of poison calculated to produce the one symptom. The results obtained thus far by research do not justify such a view, and this type of gastric vertigo often occurs in individuals whose gastric conditions do not admit of auto-intoxication. On the contrary, it rarely occurs by itself in advanced stages of atony or dilatation. There are no specific gastric states with which this type can be directly connected and fortunately the cases are rare.

The second class of cases occurs more frequently than the first and can usually be traced to some dietetic indiscretion. It seems hardly justifiable to call these cases *gastric vertigo,* for the latter is not the principal feature of the attacks. These patients have indulged in either a too hearty or an unusual diet and are suddenly seized with severe epigastric pain and pressure which is followed by intense palpitation, dyspnea, vertigo and possible syncope. There is some danger of a fatal termination in these cases, whereas simple gastric vertigo can have no such ending. The mechanism of production here is more complex than in the first class. It consists of a mechanical, or reflex interference with the heart's action due to intragastric pressure as a result of the rapid production of gas. This in turn leads to interrupted pulmonary circulation causing the dyspnea or irregular cerebral circulation causing the vertigo. The latter may also be caused by the intense fear which usually accompanies such attacks. That auto-intoxication should be responsible for some of these cases may be a possibility provided a sufficient length of time has elapsed between the onset of the attack and the dietetic indiscretion. Many of these cases, however, occur very shortly after meals at a time when fermentative or putrefactive changes in the food could not be very far advanced. Here auto-intoxication is out of the question, for it is usually a slow process, whereas the onset and course of these attacks are sudden, rapid and alarming. They are cases for the nearest doctor, and their frequency lies midway between the first and third types.

The third class comprises those cases in which the vertigo is associated with chronic gastric diseases as a momentary sensation. Such cases are numerous, but the evidence of any causative relation existing between the vertigo and the gastric disease is often very obscure. A general neurosis usually is present at the same time and the diagnosis of gastric vertigo will depend largely upon

the time relation which exists between the neurosis and the gastric disease. Should the etiology show that the neurosis existed before the stomach symptoms set in, the vertigo will probably be of the neurasthenic variety. If, on the other hand, the neurosis developed as a result of the gastric condition, the vertigo may be due to the latter in so far as the stomach can be looked upon as the remote causative factor. This, however, does not imply that this organ can be accredited with the immediate attacks, for we have seen how difficult it is to connect such an attack with the individual gastric symptoms. I am inclined to believe that in the majority of these cases the vertigo is due either to external influences affecting the special senses or originates in the central nervous system as a result of a predisposition engendered by the mental depression or irritability and general loss of confidence developed by long suffering. Agarophobia is commonly associated with the vertigo in these cases and often precedes the attacks. This loss of the sense of security is conducive to a loss of equilibrium so that such patients soon find themselves in a condition of "vertigo fear" (Schwindelangst—Brücke). Sudden fear or shock is very apt to produce disagreeable and even painful epigastric sensations which, in cases of nervous gastric diseases, may lead to nausea and vomiting. In this way, the stomach is often immediately associated with attacks of vertigo, when in reality, the rôle played by this organ is purely secondary.

It has seemed advisable to direct attention to these few facts on account of the tendency to shift upon the stomach the responsibility for a lot of nervous phenomena which happen to appear in the course of chronic gastric diseases. In this connection, Van Noorden regarded melancholia in the light of a gastric secretory neurosis, because hypochlorhydria happened to be present in twelve cases. Clozier claimed that the majority of hystero-neuroses were due to congestion of the whole abdominal system. Faber, while admitting that zones of hyperesthesia might exist in chronic gastric disease, suggests that a general neurosis must be present also. Other examples are the so-called stomach cough (Ball), loss of sight after hematemesis (Graefe), tinnitus aurium (Menière, Levan), neuralgia of all kinds (Debu) and, finally, a case of labioglossolaryngeal paralysis due to vagus neuritis, starting in the stomach and leading to bulbar myelitis (Cuffer). Suggested and then denied, these few theories are only specimens of the numbers which have appeared from time to time, and can serve to demonstrate the necessity for a detailed analytical study of the etiology and symptomatology of each gastric disease, for mere association or the effect of treatment upon such a disease cannot guarantee the existence of a causative relation between the two. Many remote effects of malnutrition may be affected by treatment of digestive irregularities and patients are naturally very apt to attribute all their ills to a deranged stomach, for no organ affects the disposition or directs attention to itself to such an extent as does this one.

When we consider, moreover, the number of pathological conditions of other organs which are said to produce vertigo by reflex action, it seems advisable to limit this possibility from any particular one, for "by reflex action" must be an uncertain explanation at best. In this connection, I will only mention laryngeal vertigo (Charcot), cardiovascular vertigo (Grasset), aural vertigo (Menière), retinal vertigo (Mendel), nephritic vertigo (Bonnier), epileptic vertigo (Hitzig), rectal vertigo (Leube), neurasthenic vertigo (de la Tourrette), and infectious vertigo (Gerlier).

## NOTES ON THE SELECTION OF A CLIMATE FOR THE TREATMENT OF TUBERCULOSIS.*

BY RUSSELL BELLAMY, M.D.,
OF NEW YORK.

No factor at our command to-day is more potent in effecting a cure, and, in the majority of cases, in ameliorating the symptoms of tuberculosis, than the influence of a proper climate. With new research laboratories planned on a gigantic scale, with their corps of workers seeking to stamp out disease, and especially "The Great White Plague," I believe that some method easy of application will be soon secured to cure and exterminate tuberculosis. Until these novel research workers tell us of their discovery, however, the general practitioner and the health boards of our municipalities must put their trust first and foremost in a land where sunshine is longest, relative humidity lowest, and yet with sufficient altitude and certain necessary atmospheric conditions to produce the essential results. The Health Board of this city, with the cooperation of such men as Lederle, Biggs,

* Read before the Alumni Association of Bellevue Hospital, March, 1903.

Loomis and Wilson is to-day doing its utmost to stamp out consumption and, at the same time, to effect cures with the limited means at its command; the establishment of its new tent colony is greatly to be commended. But, even the Board of Health with its able coadjutors is too heavily handicapped in its work by the enormous mass of foreign immigrants poured in on us weekly. Many of them come from rural districts, and take up life here, compelled to face the changed climatic conditions of a city, a climate ready to develop in them tuberculous infection. Those of us who have worked among them on the East Side, know full well of their poorly nourished bodies, with systems only too ripe for the infection to be found in the overcrowded and unsanitary quarters they must necessarily occupy.

In my opinion, infection would be greatly lessened in the city if, on sunshiny days, all employes were compelled to take their midday meal away from the building in which they are employed; or else that their places of business should provide roof gardens, or sun-rooms, for this purpose. The use of prisms, humidifiers, modern automatic ventilating apparatus and possibly the new glass paint just discovered by Galpin, especially in the construction of lofts and buildings set aside for large colonies of workers, should be more urgently insisted upon. Another suggestion occurs to me that in all factories, sweat-shops and places where the number of cubic feet of air is far below normal for the workers employed, at least once in twenty-four hours the floors should be sprayed with a solution of formalin of not less than 1 to 5,000 strength; or formaldehyde vapor should be liberated in the same space. The use of recreation piers enclosed in glass in winter seems advisable.

When we look into the climatic condition of New York and compare it with other localities, we can readily realize that something must be done if we are ever to check the development of this dread disease.

New York State, covering an area of 49,170 square miles, in 1900 had an estimated population of 7,268,894, or 152.6 people to the square mile. Of this, New York City alone, with an area of 308 square miles, had a population of 3,437,202 people for the same year, or an average of 256 the square mile. On the other hand, Arizona, occupying as it does 113,020 square miles, shows a population of 122,931 in 1900 (24,333 of which are foreign born), or an average of 1.1 persons to the square mile; Colorado, an area of 103,925 square miles, with a population of 539,700 (91,155 of which are foreign born) shows an average of 5.2 persons to the square mile, or Denver, covering 54 square miles, having a population of 150,000; New Mexico, with an area of 122,580 square miles and a population of 195,310 (13,625 of which are foreign born, shows an average of only 1.6 people to the square mile).

The statistics for probably the worst month in the year for the growth of bacillus, *i.e.*, March, are as follows: In 1901, March showed only 49 per cent. of sunshine, or 182.7 total hours.

Under the existing conditions of life to-day I believe it is impossible to cure tuberculosis in the City of New York, and I look upon it as an error of judgment for any medical man to keep a case, especially in its early stages, in this city. For nearly one year I lived in that region of the United States in the Rocky Mountain chain, extending from the middle of British Columbia, on the north, to the City of Mexico. During that time I had the opportunity of studying carefully the character of this region in all its particulars, with a view to finding the most suitable place for the treatment of the different stages of tuberculosis. During my investigation I became convinced of the advantages, especially offered by places in Colorado, New Mexico, Arizona and Western Texas. I have also spent some time and pursued my investigations in the Adirondacks and parts of North and South Carolina, and in my opinion, residence in these districts, under proper conditions of hygiene, sanatoria and tent life, helps to prolong life, ameliorate suffering, and probably effects some cures. These sections, however, compared most unfavorably with the selected territory of the Rockies previously mentioned, on account of the lessened altitude, unusual humidity, fogs, great rain and snowfall, the increased wind currents, markedly variable temperature and, consequently, the decreased number of days of sunshine and strength of sunrays, in some instances also, the proximity of large centers of civilization.

With the vast wealth that New York City commands, it seems not only possible, but imperative, that large sanatoria should be built in places best suited for the cure of this disease. It matters not whether the colonies to be established be municipal, state, philanthropic or national—this is a question that cannot be too strongly presented to the community, for it touches every man, woman and child who resides within the bounds of our city.

A consideration of the geography and meteorology of the Adirondacks seems useless, as every medical man interested in this subject is absolutely familiar with this region. Undoubtedly the proximity to the St. Lawrence Valley tends to greatly increase the moisture and rainfall of this district. Then, the altitude is not to be compared with that of places west of the Mississippi. The work of Trudeau and the elder Loomis is quite familiar to all of us and, in passing the Adirondacks, probably the best places are the Adirondack Cottage Sanatorium, accommodating about 100 people, and the Saranac and Lake Placid regions, with a relative humidity generally of about 73 per cent.; 132 clear days are observed, 104 partly cloudy and 129 cloudy. Rain falls from 30 to 40 inches. One might also mention the village of Ray Brook, situated in the heart of the pines, a short distance from Saranac Lake. The air here seems antagonistic to the growth of the bacillus as it is never found in the

cattle of the region. The altitude is about 2,300 feet, the altitude of Saranac Lake being about 1,800 feet.

"Of 173 patients 45, or 26 per cent., were discharged as cured; in 79, or 45 per cent., the disease was arrested; 39, or 22 per cent., were discharged in an improved condition; 4 were doubtful and 1 died.

In 40 incipient cases, after a residence in the sanatorium of from 3 to 17 months, 33 were discharged cured, in 6 the disease was arrested, and 1 improved.

In eighty-four advanced cases twelve were cured, in fifty-five the disease was arrested, fourteen improved and three did not improve.

In seventeen far advanced cases the disease was arrested in six cases, ten improved and one did not improve.

Of 141 cases 133 gained on an average of fourteen pounds in weight, five lost weight and three remained stationary."

A charitable philanthropy, much to be commended, now nearing completion, is the Stoney Wold Sanitorium, a station or two above Paul Smith's. It will undoubtedly fill a long-felt want in caring for the more deserving classes of the poor. Unfortunately, it is situated in the wake of civilization, and one will be almost able to shake hands with the patients from the railway carriage, and certainly patients cannot escape breathing the smoke-laden air from the passing trains. The consumptive must avoid civilization, so to speak. His home for at least a certain portion of the year, if we could achieve the ideal, would be in the fast-fading wilderness.

The district near the town of Liberty, New York, should be mentioned. The soil is loam and clay, and the average altitude is about 2,300 feet. The snow generally remains most of the winter. The statistics of the Loomis Sanitorium undoubtedly point to this as being a fair place for the tuberculous.

Advanced cases seem to do very well in Aiken, S. C., a very low altitude, but, for unexplained reasons, quite the driest place east of Denver. The mountains of Western Pennsylvania offer some advantages, while the pine belts of North and South Carolina, probably influence some cases.

Northwestern North Carolina, with an altitude of 5,000 feet, especially near Cæsar's Head, Blowing Rock and Hendersonville is also good, provided one can get good accommodations. The best way to pass the time in either of these places is in tents or log cabins. Asheville, N. C., has been thought well of by some medical men for years, but it seems to me to be overcrowded, and has an altitude of only 2,339 feet, a relative humidity of 65 per cent., and plenty of red porous clay.

Occasionally a tuberculous case will do well at the seaside resorts, and the Island of Nantucket offers a balmy climate in summer, while Southport, near Wilmington, N. C., with 54 per cent. of sunshine, makes an all around delightful annual resort, if one can believe the seashore is to be advocated.

Dr. Cohen mentions Boerne, Texas, as an admirable place, and recently I have heard good things said of San Angelo, in Southwestern Texas. Many English people have gone there. The life is good, and the encouragement of outdoor sports adds great charms to the place. In passing, one should mention El Paso, Texas, with 3,754 feet of altitude, 49 per cent. mean relative humidity, moderate winds, protected northwest and south by the Rocky Mountain spurs. It is becoming quite a popular resort from September to May for those who are going West, but wish to try a moderate altitude for a few months. Laryngeal cases are said to do especially well in this locality. The heat of Texas makes it a land to be avoided, however, in the summer months.

For almost every case of tuberculosis, however, especially when it is now possible to make a railroad journey of three days so comfortably, the ideal vantage ground of the world to me today is the State of Colorado and the Territories of New Mexico and Arizona. So important do I look upon this district that I deem it advisable to describe in detail the country, the life to be found there and the permanent advantages afforded the sufferer—the anemic, the chlorotic, the predisposed, as well as the sufferer from tuberculosis.

Undoubtedly, either through travel or reading, we are all of us more or less familiar with the great West, but I would like to call your attention briefly to that portion of it which I consider ideal for the tuberculosis patient, namely Colorado, New Mexico and Arizona. We will take Colorado first. This State is situated in the central belt of States in the Rockies, and you will find that in Colorado the highest development of the Rocky Mountains is reached. It abounds in numerous lofty peaks, many of them over 14,000 feet elevation, notably Pike's Peak and Long's Peak. The eastern part of the State is a vast plain, sloping away to the Kansas line, with an average elevation of 4,500 feet. The western and central portions of its area are occupied by an intricate plexus of wild and irregular ranges, enclosing valleys known as "Parks," most of which are extremely fertile and well wooded, and it was in these parks I spent a most enjoyable sojourn, and about which I am especially enthusiastic. The delightful life one can lead here recalls memories that only the realization of one's ideals can equal. The northwestern corner of Colorado is the land for the boy and girl between the ages sixteen and nineteen years. A summer, the nights of which are spent in a sleeping-bag in a tent, or lean-to, would destroy all chance of infection, which children of the more highly bred, may have in their bodies. These parks are hemmed by thick forests of spruce and fir, and the very air seemed so heavily impregnated with the delicious antiseptic vapors as to make it, in itself, almost possible to sustain life. Ozone is

said to be greatly increased in these piney woods by certain chemical changes, which take place in the leaves, about which very little is known as yet, and which yield a salubrious effect. The sun's rays are hot, invigorating and delightful in the summer. Many early cases are sent up into these picturesque park lands in the northwestern corner, where I camped among the multicolored flowers and rushing streams, the balsams, firs and cedars. The projected railroad between Denver and Salt Lake City will make this land, now only available by pack trains, the vantage ground for the summer, and for a great sanatorium, National, I trust. The altitude is from 7,000 to 11,000 feet. The coldness and crispness of the air of these higher altitudes gives out a drying, tonic effect, stimulating and strengthening the invalid, and exercise a most inhospitable attitude toward this bacillus and the germs of pus. I have seen miriads of mosquitoes in a belt a mile wide, feeding so furiously as to stampede the pack-horses, but as the sun faded over the hill all insect life was stilled, and we slept with the greatest comfort. With all this the voice of nature is supreme, which means local immunity, the density of the population being hundreds of times less than in a city, and the life absolutely free from chances of infection. The effect of the change from the cities is good and the "advent of a tuberculous fire, which had rekindled in Denver, has been effectually stamped out by a sojourn in these parks."

Speaking generally of Colorado, however, the precipitation of winter is almost wholly in the form of snow. In the plains and valleys it is light, but, of course, this fall is very much heavier on the mountain slopes, and is apt to last into April and May. The rainfall in the mountain regions increases in July and August, but take it altogether, the climate is dry and healthy. There are no fogs, a low atmospheric pressure, an average wind movement of about seven miles an hour, and a marked difference in the sun and shade temperature; for instance, at two o'clock in the morning one requires the heaviest blankets and coats to keep warm, while at twelve o'clock noon it is almost impossible to ride in the sun. Aside from being a favorable climate for tuberculosis, Gardner concludes that the climate of Colorado exerts a most beneficial effect in all diseases of the gastro-intestinal tract characterized by diarrhea, *i.e.*, enterocolitis, cholera infantum, dysentery, etc., and the death-rate among infants and children from these causes is excessively small in Colorado as compared with other States. Then, too, the milk supply, due to non-septic air, moderate thermometric range, and, in most cases, the splendid physical condition of the cattle makes possible a far better nutriment in bottle-fed babies; while the mother who nurses her child has the added advantage of healthy, life-giving environment, and must necessarily impart to her baby the vigor derived from air and sunshine. You can readily understand, therefore, that the climate of Colorado tends to encourage and make possible a more perfect and higher physical development in the child.

To return to our subject-matter, you can readily see from this brief description, that Colorado is eminently suited to the requirements of our tuberculosis patients. Let us take Denver, for instance, which I always think of as "The Parlor City of the Plains," and which is justly famous as "The City of Beautiful Homes." Many consumptives are attracted to this city, owing to its beauty and healthfulness. Certainly the number of active, wealthy and useful business and professional men who have recovered their health and strength in its environments, and have finally made Denver their home, constitute one of the strongest endorsements for the healing properties of Colorado's climate. It shows a record of 42 per cent. of clear days, as against New York's 27 per cent.—New York double the amount of cloudiness. Then, there are no lack of splendid accommodations, either in hotels or boarding houses, the best board in private houses ranging from $8 to $10 per week.

I cannot too strongly impress upon you the cruelty, if not danger, of sending a patient to any resort if he has not the means of procuring all necessary comforts, at least until he has so far recovered as to permit of his engaging in some pursuit, which will aid him financially. The consumptive, as a rule, is imbued with the idea that the change to a good climate is going to cure him very shortly, but we who know, realize the months, and sometimes years, which will ensue before a cure is effected. The more advanced the disease the greater responsibility rests upon the doctor in recommending a change, unless the patient's finances can stand the drain, which is sure to come. The Oakes' Home for Consumptives in Denver is well thought of.

Colorado Springs, a city of 25,000 inhabitants, with an altitude of 6,022 feet, offers, in my opinion, the greatest all around advantages of any place in this country. Its days of perpetual sunshine, its charming life, its great dryness, and I do not now recall one cloudy day in the spring and summer of 1894: its environs, delightfully hospitable people—everything done for the invalid by those who are now cured, makes it stand foremost to my mind as an ideal place. It should be avoided, however, by those over fifty years old, and the advanced cases, unless they have been accustomed to living in high altitudes, say of 3,000 feet, for at least several months. Probably one of the best hotels in this country now stands upon the ashes of the old antlers. Broad avenues, mesas, country clubs, polo, coursing with hounds, beautifully furnished houses, with an ideal climate, associated with many of Nature's grandest works—canyons, formations, and curios (for instance, "The Garden of the Gods") —the only flaw being an occasional wind-storm. Females should be well veiled, and while driving should avoid the eye of the gale. Colorado Springs has no mud. Snow in the morning is evaporated or soaked into the ground within

three hours. I understand that General Palmer has granted a number of acres near his very attractive home "Glen Eyre," between the "Garden of the God" and Manitou Springs, for a sanatorium, but until this section has a great reservation with sanatoria or tent colonies in its vicinity, I would suggest it as best suited to the wealthier class of invalids. Patients should take life easily at first until they become acclimated. To-day I know of several cases of advanced tuberculosis, who, after a sojourn of from one to five years in Colorado, are now able to live in the very heart of New York. Drs. Gardner and Solly believe that Colorado Springs affords greater opportunities in the earlier stages than any other place in the foot-hill region. As I look back upon the hours I spent at Colorado Springs, with its luxuries, its varied charms and its glorious climate, I can only call it the "Newport of the Rockies—"The Paradise of the Mountains."

From Colorado Springs one goes to Manitou Springs, a delightful place sheltered by Pike's Peak, but lacking many of the advantages of Colorado Springs. Dr. John A. Robison is especially enthusiastic regarding this place, and calls our attention to the following cases: "I wish to relate one experience that I have had in sending patients to a high altitude and its effect upon the hematopoietic processes. I had under my care two young women with predisposition to tuberculosis. About two years ago one became profoundly anemic, and there was a slight tuberculous deposit in the right apex. I sent her to Mont Claire Sanitarium at Manitou. She remained there all winter and the following spring, and since returning to Chicago has been in perfect health. I never saw such a transformation, with the exception of that in her sister. When she went to Manitou she was chlorotic, her lips were almost bloodless. When she returned she had rosy cheeks, had gained in flesh, the tuberculous deposit had apparently cleared up and she has been in perfect health since. Last winter her sister became chlorotic, but there was no deposit in the lungs, and I sent her to Manitou. She returned in the course of a few months, having gained fourteen pounds. Her cheeks were rosy, her lips red, and she has retained her health ever since. These are two examples which show that the change of climate from Chicago to Colorado quickened all the blood-making processes, and it did not require a blood-count to demonstrate it."

Before leaving Colorado, I would like to say a few words regarding Boulder, where is situated the State University. This town also offers many advantages and attractions. The places at Middle Park and South Park, where the altitude is from 7,000 to 8,000 feet, are also to be considered, especially in the summer time. Glenwood Springs, twelve hours west of Colorado Springs, offers fair advantages, but is recognized more especially to-day as the best outfitting place for camping parties going to the northwestern part of the State. Estes Park, at an elevation of 7,500 feet, San Luis Park, at an elevation of from 10,000 feet, surrounding a beautiful lake, might all be mentioned as healthful spots. One must not forget the sanatoria at Falkenstein Gerbersdorf, showing an average of 51 per cent. of cases benefited, and Reibolsdorfer, with a record of 56 per cent. of cases benefited, each at an altitude of from 1,375 to 2,300 feet, with Colorado at 70 per cent.

We may now take up New Mexico. The whole surface of this territory is generally mountainous to the Arizona line, though a central valley of an average breadth of 20 miles extends across it from north to south. This valley is hemmed in by the main chain of the Rockies, many of the mountain peaks here rising to an elevation of from 10,000 to 12,000 feet. The higher ranges are covered in many places with pine forests, and lower, with cedars and occasional oaks. The climate is generally temperate, the rainfall, which comes very largely in July and August, averaging about 13 inches. Very few points receive as much as 20 inches during the year, the greatest rainfall on record being 35 inches at Old Camp Grant, N. M., in 1871. The winter rains begin about December, and practically end in March, and rarely fall as heavily as during the summer, being more or less irregular. The wind movement is less than in Colorado, but the great sand-storms sometimes occurring in the spring make it objectionable. The whole territory is practically one of sunshine and sand. So pure and dry is the atmosphere that meat hung out in the air to dry will not decompose. It is simply a splendid place for consumptives; the natives themselves seem to be entirely immune from its infection, and really do not know what the word "consumption" means in this connection. The winter climate from Albuquerque, south, is superb, but during the summer it is too warm for most patients, and its distance from most centers of interest, combined with the eternity of sand and sunshine, renders the life here sometimes a little monotonous. The only pleasure one could derive from the country would be in "roughing it," but, of course, the tuberculosis patient could not endure such fatigue at the start. By far the best part of New Mexico, considered from the standpoint of a health resort, is situated in the northern portion of the territory. The winters are mild and open, with scarcely any rain or snow, and the summers are cool and delightful. The thermometer during the winter averages about 45° F. at noon, while in summer it rarely registers above 80 degrees.

Santa Fé, the principal city, is situated in the vicinity of the loftiest peaks in the territory, and one finds it a delightfully quaint old place, still half Mexican. The summers here are enjoyably cool, dry and exhilarating, though the altitude (7,000 feet) is too great for most patients. St. Vincent's Sanitarium might be mentioned in connection with this city. Here the best of accom-

modations can be obtained at fairly moderate rates.

Albuquerque is another of the chief cities, and lies but twenty-four hours from Denver, at an altitude of 5,000 feet. To my recollection the hotels are not of the best, though there are many good boarding houses. The winters are warm and pleasant in this locality, while the summers are fairly hot, although the nights are always pretty cool. Albuquerque probably has the best climate in the southwest, although the fact that the place is overcrowded with invalids, and the lack of good accommodations is noticeable, makes the place more or less undesirable.

Silver City seems to me to afford especial advantages to those suffering from tuberculosis. It has an altitude of 5,800 feet, and the winter and spring climate is excellent. While I have never visited Silver City, I have corresponded with a patient there recently, who tells me the accommodations there are exceedingly crude, the difficulty in getting the best food very great. From what photographs I have seen of the place I should judge it to be a bustling mining town more than anything else. Throughout this region numerous small parks are to be found, and these offer a most agreeable respite during the summer months. Most of the houses are adobe huts, and it is advisable to provide a tent with sleeping-bags for the patient going into this district.

There are only two other cities in New Mexico worth mentioning, viz., Las Vegas and Las Cruces, both possessing many excellent advantages.

One notices on arriving at the resorts of the great southwest, where the altitude is over 4,000 feet (for instance, Colorado Springs, Denver, Albuquerque, Santa Fé, Silver City, etc.), how distinctly rare the air is. This, with its lessened amount of oxygen, makes us take the deep breaths, thus increasing the circulation, opening up the minutest ramifications of the lungs, and rapidly increasing chest expansion. Then, too, is observed the healing, invigorating and stimulating effect of the brilliant sunshine, sometimes as high as 120 degrees, and when the shade is sought the marked difference in temperature is felt. Occasionally the air may have a few particles of dust, but when we analyze it we note its great purity, and the total absence of fogs and mist. The sun-rays of the mountains and foothills of the Rockies contain a large proportion of the blue end of the spectrum, and these rays have marked bactericidal and germicidal powers. It is these rays that undoubtedly give the marvelously gorgeous tints to the gentians, daisies, and other wild flowers so familiar to all of us who have camped out in the summer at high altitudes. The rapid action of light, the early dawn and the prolonged twilight are two especial features of Colorado Springs, and mean for the patient outdoor life and pleasure. In summer, where most of the rain falls in almost cloudburst effects, the air seems greatly cleansed, and this cleansing, if at all necessary, seems to last for the year.

The rainfall of the foothills region east of the Rocky Mountains ranges from 10 to 18 inches, and it increases slowly toward the one-hundredth meridian. Eastward of that meridian the annual precipitation varies from a little under 20 inches to about 60 inches on the Florida and Gulf coasts. There is a gradual decline both from the Atlantic Coast westward and from the Gulf Coast northward. The diminution in fall from New Orleans northward to St. Paul is 32 inches; from Eastport westward to St. Paul, 12 inches.

I have always noticed that while snow came rarely and was rapidly evaporated, blown away or soaked into the sandy soil, it seemed to markedly intensify the light and increase its powers of reflection.

But we must not overlook Arizona, which is preeminently the land of sunshine. The physical features are: The mountain system appears at the southeastern corner of the Territory and extends in a general northwesterly direction to the borders of Utah and Nevada. More than half the territory is above the 5,000 foot contour line, and forms a part of the great plateau region west of the Rocky Mountains. About one-third of the territory is sandy plain gradually rising in elevation from less than 100 feet at Yuma, to a rather narrow bench or mesa that faces the plains about 180 miles northeast of Yuma. The elevation of the mesa ranges from 3,000 to 5,000 feet above sea-level. Beyond it to northeast is the high plateau of Arizona. Annual rainfall of this region ranges from 10 to 20 weeks. About 35 per cent. of the rain falls in July and August. May and June are generally the months of the least rainfall. The summer rains are essentially a feature of the mountain and plateau systems, and are believed to be due largely to local convection induced by excessive insolation on the barren, rocky surface of the mountain sides and summits. The winter rains are believed to be due to migratory areas of low pressure pertaining to the general system of storm movement. The character of the winter rains, whether light or heavy, depends largely on the frequency of atmospheric disturbances. Yuma, in the heart of the desert, shows 84 per cent. of sunshine. Mr. Whitelaw Reid compares the climate of this territory to portions of Egypt. He believes it to be even sunnier, drier and more delightful than the district around Luxor or Assouan. I have traveled all over the territory, and spent some delightful days shooting in the famous wide valley, 40 miles northwest of Prescott.

Prescott offered a few years ago no special advantages to the health-seeker; it was purely a mining and ranching town and was slushy and muddy in the spring.

Flagstaff, with its 7,000 feet of altitude, is charmingly situated in the wilds of mountain forests. The eastern invalid can look especially to Tucson, Phenix and Crede for comfort, climate and charm. Phenix is in the midst of an

oasis where the air is somewhat more humid, which is brought about by the increased irrigation. Tucson, with 42 per cent. humidity, is 121 miles southeast of Phenix, is 2,300 feet high, and is quite a modern southwestern town. Arizona possesses all the elements of a climate suitable for advanced cases—those along in life or where the condition of the heart muscle is a consideration. The fruits and flowers of Phenix have alone made it famous. Arizona is crossed by two great railways, and its sanddunes are becoming more and more an object of interest to transcontinental travelers. The ranchman and the eastern boys will rapidly open up the territory. I feel safe in predicting that many charming little towns will soon spring up where the altitude is below 3,000 feet—the winters will be balmy and the summers will not prove oppressively hot, as irrigation and humidity must be considered. The rainfall is often less than seven inches.

The place most highly spoken of in Arizona, and which, I trust, will soon have railway connection, is Oracle, 38 miles from Tucson, has 4,500 feet altitude. One writer calls it a "pretty mountain nook embowered with live oaks:" it undoubtedly possesses great advantages.

In parting with the wild regions of Arizona, so essential to-day in curing tuberculosis, my mind naturally reverts to the question of tents. Let me mention the Fitch & Abercrombie waterproof silk tent, 7x7 feet, and weighing but seven pounds. I have used it and find it perfect. The Munson sanitary tent is also excellent. Dr. A. M. Holmes, of Denver, deserves the thanks of the profession for his new sanitary tent cottage.

After living for months in the ideal district of Colorado, New Mexico and Arizona, and studying the weather bureau charts at home, the advantages to be derived from this climate by the tuberculous seem to me absolutely convincing. I believe it is imperative that a philanthropic or national reservation with tent colonies should be established in some part of this locality. Recruiting stations could be opened in the great cities and State sanitoria could send selected cases to the Great Western Tent Mecca. Our government spent millions of dollars in Cuba to drive out malaria and yellow fever for the Cubans and it now seems imperative that it should appropriate moneys for a southwestern reservation for the consumptive.

I am very much indebted to excellent papers by Dr. Waxham, of Chicago; Dr. Denison, of Denver; Drs. Gardner and Solly, of Colorado Springs; to the System of Physiological Therapeutics; to the chief of the U. S. Weather Bureau and his staff of the New York office. I am especially grateful for the courtesy, kindness and encouragement shown me while preparing this paper.

*Modified Summary.*—In summing up the advantages to be derived from these places by the consumptive, let me impress upon you a few points:

1. Consumptives with a rapid breaking down of lung tissue should avoid high altitudes. So also should those of neurotic temperaments.

2. Those with especially developed cardiac lesions, with a marked tendency to a disturbance of cardiovascular balance, should avoid high altitudes.

3. Those completing the fifth decade, where the capacity of muscular exertion is considerably limited, should avoid high altitudes, although I have heard of many cases being taken to Colorado, recovering and taking up their life there.

4. Laryngeal cases do better at the low altitudes.

## HYPNOTISM AND HYSTERIA.*

BY WM. BROADDUS PRITCHARD, M.D.,
OF NEW YORK;
ADJUNCT PROFESSOR MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, SMITH INFIRMARY.

In response to the request of several members of the class, I shall devote the hour to an effort to put you in touch with a working knowledge of the subject of Hypnotism, a sort of fantastic phantasmagoria in the minds of the uninitiated. The medical profession is by no means an unit in its professional estimate of this subject, nor is the lay mind any more unanimous. To the great majority of those who accept as a fact the state or condition known as hypnotism, the phenomenon is so associated with the mysterious, the weird and the uncanny as to leave the student mind in a state of utter chaos as to any tangible or material explanation.

There are many who are ignorant from investigative inaction.

It is instinctive with many to fight shy of the unknown and inexplicable, to let some other fellow go first. We hesitate to enter unexplored territory. A third, perhaps, of the masses, and not a few physicians, are arrant sceptics, denying altogether the existence as a genuine phenomenon of hypnotism in any form or degree. To such sceptics it need only be said *circumspici* "look about you." The most positive and convincing proof is easily at hand, and in limitless abundance. Not to have seen a thing is no evidence of its non-existence.

Much of the mystery which breeds this doubt and this instinctive opposition can be eliminated by a proper method of approach in the study of the subject. Similar, if not essentially identical states, are familiar and accepted in the experience of nearly every one, as, for example, in the transient, dazed state of so-called absentmindedness, in sleep-walking, and in sleep-talking, in states of post-epileptic automatism and in hysterical trance. All these are ecstasic states. For the moment or the hour the individual stands outside himself. To admit this, and it would seem a quod erat demonstrandum, is to accept with clearer understanding what follows. In proportion as one is mentally stimulated by a special idea or thought, all other mental activity is repressed or

* Lecture delivered at the New York Polyclinic.

inhibited or paralyzed for the time, the result being a state of preoccupation or slight trance. The dervishes of Arabia, the fakirs and priests of India, the religious disciples of central Japan, and other orientals develop under certain circumstances, states of self-hypnotism in remarkable degree and profundity. The religious trances and ecstacies of the Southern plantation negroes are identical in explanation and character. The soldier who marches into action to the strains of martial music is hypnotized in a way. The friend who suggests to a friend the doing of a certain thing not previously contemplated illustrates the initial border-line between spontaneous volition and suggestion. These, it may be urged, are all states of self-hypnotism or auto-suggestion. What is the difference after all? It seems to me a case of tweedle-dum and tweedle-dee. If the susceptible individual can, within himself, develop these conditions, why should it not be possible from extraneous suggestion? As a matter of fact, I am not sure but that all states of hypnotism are autogenous, the operator or hypnotiseur simply suggesting to the suggestibility of the subject. The argument is equally tenable that all suggestion or hypnotism is extraneous in origin through extrinsic sense impression, as in the effect of martial music on the soldier.

The phenomenon is not limited to man. The lower animals are exceedingly sensitive. I have seen the late Dr. Landon Carter Gray hypnotize at one seance a rabbit, a frog, a pigeon, a lobster, a canary and a man. I have myself hypnotized frogs, birds, dogs and other animals. The familiar child's trick of stretching a chicken's neck out, bringing the bill to a certain crack in the floor or line in the sand, gently stroking the head or body at the time, then leaving the chicken stretched out unrestrained for several minutes, is an example. The snake charming a bird, the man controlling a wild beast with his gaze, are not necessarily myths, to my mind, both allowing of a quasi-rational explanation in hypnotic influence. Mowglie's control of his fellows of the jungle, as described in one of Kipling's recent publications, quite graphically illustrates this power, although the illustration is lacking in scientific value or force.

Another deterrent influence, of no mean weight in its effect in delaying our knowledge of the subject, is the red flag of danger which has been waved along the line of research in this field. "Much harm can be done to the subject:" "his mental integrity may be seriously impaired;" "his will power utterly destroyed and he himself degraded to the purposes, meritricious and even criminal, of the operator." There is no evidence whatever in support of such doctrines, and very much evidence directly to the contrary.

Hypnotism, beyond question, although very limited in its field of usefulness, has accomplished good; that it has done harm, when legitimately employed, remains absolutely without proof in specific instances. There has been much of empirical damnation. As a result of careful investigation, I am convinced that those who cry loudest Wolf! Wolf! know least about it. In this instance, as in many others, fear is born of ignorance. Employed illegitimately and for ulterior purposes, I am not sure but that its results might be harmful. To put morphine in the hands of the quack or layman, or to give children matches to play with, of course involves danger. The layman has no business handling morphine, and he who puts matches into a child's hands invites trouble. Admitting, for arguments sake, that there is any danger, are we therefore to discard it altogether? If so, to be logically consistent, we should, as Hirt suggests, discard ether, chloroform, opium, strychnine, and indeed, practically all our therapeutic resources. In justice to myself I wish just here to discount the possible charge of enthusiastic faddism. I am no enthusiast. I simply want to see fair play. Quite as much harm has been done in delaying and obstructing a calm judicial adjustment of values, by the optimist as by the pessimist. There are hypnotists "run mad" beyond question—men, who, if they are to be believed, can cure anything from a cold to a carbuncle, by hypnotism. Such enthusiasts possibly have hypnotized themselves. This, at least, is a charitable explanation of their utterly visionary and extravagant assertions. "In medias res tuta est." Somewhere between the two extremes of enthusiastic advocacy and materialistic doubt lies an agent undoubtedly entitled to a legitimate, though limited, place in our useful therapeutic resources. The youth of the subject affords another explanation for our ignorance. Hypnotism proper dates back only some 200 years, ab initio. It was first called Mesmerism. Franz Mesmer was born in 1753. He enunciated the doctrine, in explaining certain phenomena induced by him in susceptible subjects, of a magnetic fluid, atmospherically communicable, from operator to subject, which gave to the former complete control over the volition of the latter. He was a gigantic fakir, scientifically at least, but, as in other instances, some good thing may come out of even such a Nazareth as that. We owe something of value to Hahnemann and even to Mrs. Eddy. Hypnotism proper dates from the writings and teachings of Braid in 1841. Liebault, following Braid, reviewed and further elucidated the subject in 1866. To Bernheim's work, published in 1884, less than twenty years ago, however, we owe more than to any other source, a scientific estimate and systematized elaboration of the subject. Charcot, Richer, Haidenhaim, Forel and others have added much to our working knowledge. Much remains to be done, and effort should be encouraged and not repressed.

Coming directly to the subject and to a résumé of our present knowledge, two important factors present themselves for consideration: First, to what extent does hypnotic power exist in the operator, and to what extent does hypnotic susceptibility or sensitiveness occur in the subject? As to the former, I believe with Hirt and others,

that hypnotic power is primarily quite limited. I believe, however, that it can be acquired by cultivation and self-education quite readily. The hypnotiseur must believe first, in hypnotism. He must have a legitimate purpose in view; he must have self-confidence, which is greatest, of course, when born of experience. Sceptics are incompetent, and to them failure is predestined. Bernheim says that the physician who cannot hypnotize 80 per cent. of his material does not understand his business. This I believe to be an extreme view under any circumstances. Properly interpreted it means simply that Bernheim had had much experience. A certain degree of inconstancy in results must remain, for the reason that the personal equation of both hypnotiseur and subject is itself inconstant. As to susceptibility on the part of the subject there is an extreme divergence of opinion as to groups and classes. How much of this is due to the attendant circumstances surrounding operator and subject is hard to determine. For example, Charcot and Richer held that hysterical subjects were easily hypnotized. American authors and many English and German observers disagree with this conclusion. Charcot's experiments were at the Salpetriere, a hotbed of hysteria amidst a nation of hysterics. The Latin races are peculiarly susceptible to hysteria and to hypnotic suggestion. These facts must be taken into consideration. The racial difference should never be overlooked. Dana, Church and others among American authors, state that children are peculiarly sensitive to hypnotic influences. This I believe to be absolutely at variance with the facts and the principles of the whole proposition. It is universally conceded, whether from experience or acquiescence, that idiots, imbeciles and the weak-minded are insusceptible to hypnotic influence,—on a priori ground, children are equally, or, at least, proportionately insusceptible, and, as a matter of fact, so far as personal experience goes, they are exceedingly difficult subjects. The subject is susceptible or sensitive in proportion to his intelligent understanding of and cooperation with the operator's purpose; he must be without fear of the effects; must have confidence in the hypnotiseur, must be capable, by fixing his mental attention, of a cooperative understanding. There should be the most perfect and frank rapport between operator and subject. Absolute cooperation is not essential in the peculiarly susceptible and educated subject, but as a rule, it is necessary. The percentage of people taken at random from the masses, who are susceptible to hypnotism varies widely from 20 per cent. to 80 per cent. It is necessarily an inconstant and widely variable percentage, because of the importance of the personal equation and relation between operator and subject.

The method or technic varies considerably also, although the salient idea or principle is the same always. Braid's method was to exhaust by fatigue the visual sense, the subject being required to look steadily at some bright object (a coin) held a few inches or feet from the eye,—the distance makes no difference, although certain text-books would lead you to believe that six inches is the limit. Luys used revolving mirrors in a darkened room. Richer employed flashlights, Charcot, flashlights or loud sounds on a gong or tomtom. Bernheim employed the fixed gaze, requiring the patient to look him steadily in the eye, he meantime employing suggestion, telling the subject that he was getting sleepy; that he was asleep, that he could not open his eyes, etc. Stroking the head, face, or limbs is often employed as an adjuvant means to the desired end. The employment of monotonous sounds, as the ticking of a watch, or striking of a gong, is at times successful. Hirt's method of utilizing the psycho-physical effects of electrical sensations in obstinate subjects demands special mention as being both ingenious and practical. Dana, I am told, employs a lighted candle in a darkened room. My friend, Prof. Adler of the Smithsonian Institution, called my attention to the technic of self-hypnotism practised by the llamas of India as illustrated in Kipling's "Kim," where the llama could self-induce a state of subconscious trance by practising a certain method of forced inspiration.

The arbitrary divisions of hypnotism into different stages is, I believe, relatively unimportant. Later on it may prove to be of some technically scientific value, but, so far as therapeutically beneficial results are concerned at present, it seems to be immaterial as to whether the patient or subject is in the lethargic, cataleptic or somnambulistic state. Bernheim gives nine stages of varying degrees of hypnotism. His ninth stage is the only one of practical importance, representing as it does, a state of posthypnotic suggestion by which the subject is kept under the influence of the hypnotiseur when personally absent or separated by either time or distance.

What good does hypnotism do? This is the final and all important question. It has been successfully employed for the relief of various neurasthenic and hysterical obsessions; the phobias, functional disturbances of the senses, anesthesiæ, paresthesiæ, hysterical motor pareses, conditions notoriously difficult of relief by other means. The results attained in these fields suggest an almost limitless possibility of extension. Indeed, its importance as a therapeutic resource lies not so much in what has been done, as in what may be done. There seem to be certain quite positive contraindications to its employment. In the delusional insanities and in organic and toxic nervous diseases, its employment suggests not only an insult to intelligence, but an agency pregnant with much evil. The induction of surgical anesthesia for minor operations, the minimizing of labor-pains in parturition are both accomplished results according to the published reports of reputable observers. The regulation of menstruation and the control of constipation by hypnotic suggestion, claimed by Forel, are suggestive as to the

direction in which the field of application may be ultimately further widened.

Having reviewed the general aspects and principles of the subject, let us see to what extent these principles may be illustrated by example. The patient before you has a most interesting history, which briefly summarized is as follows:

X. Y. Z., aged twenty-one years. Electric work. El. R. R. Cough and dizziness and general bad feeling in Oct., 1902. Consulted one of the staff at Roosevelt Clinic, who pronounced symptoms due to goiter. Told operation was necessary, and if not done he could not live long. Operation done November 7. Goiter removed followed by partial aphonia. Second operation done February 10, on other side of neck, to relieve some cosmetic defect from first operation. Both operations under ether. Total aphonia following second operation, which continues and on the day following he was seized with cramps in legs and arms, feet and hands (typical flexor contractions), also in face. These continued daily for twelve days, when he was given drugs hypodermically to relieve. One week later the contractions returned, but in very short paroxysms. Since then short attacks about every week. On March 26 he had a fit of some kind: "black in face, eyes rolled back, muscles became rigid, unconscious for half an hour or more." Ever since the twelfth day after last operation has had numbness of second finger of left hand, limited sharply at metacarpal joint. Also similar sensation but more peculiar in distal phalanx palmar surface, right thumb, absolute joint limitation also. About sixteenth day after operation, developed area of exquisite painful sensitiveness about size of silver dollar on anterior thigh, left leg, about 1½ inches above the knee. Some swelling apparently, but no fluctuation, redness, etc., and in three days had disappeared, leaving no sign, no recurrence. Has had frequent feeling as of choking, lump in the throat. At times much depressed, and has "spells of breaking down," cries and is very nervous, feels as if he "didn't care for anything," and wants to die. Often lies awake two or three hours on retiring, and often sees visions floating about the room, lights, machinery at work, etc. Several varieties of visual hallucinations, but always knows it is his imagination. Can drink water, milk, ginger ale, and, indeed, anything but tea and coffee, either of which chokes him. Has found a spot just above clavicle and to the left which if touched makes him cough. Concentric limitation of visual fields. The diagnosis of postoperative major hysteria is quite obvious.

He was referred to me by Dr. Dougherty, of Dr. Quinlan's staff. The case seemed to me to be one peculiarly likely to be benefited by hypnotic suggestion. I found the patient an exquisitely sensitive subject, passing readily into the somnambulistic state at the first seance. In this case as in all others, I employed the same procedure. I first explained to the patient what I intended to do, assured him as to the absolute absence of danger or discomfort, and asked his intelligent cooperation. I employed as usual the Braid method. I made no suggestion whatever during the first seance. I try to get first the absolute confidence of the subject. The second time I hypnotized this patient I suggested to him that he would find the left thumb much improved as to the anesthesia; the third time I suggested complete disappearance of the thumb anesthesia, and a diminution of the trouble with the second finger of the other hand. To-day I shall try to get rid of these sensory disturbances altogether. He tells you that the thumb is now all right and the second finger much better. I shall next take his aphonia and gradually, one at a time, shall rid him, I think, of most of his ills. I place him in a comfortable position for a nap. I hold this ophthalmoscopic lens before him thus, three or four feet away, and tell him to look steadily at it, and to go to sleep, that his eyelids are getting heavy, that they are closed, that he cannot open them, that he is asleep. You see him, gentlemen, fast asleep, apparently, at least. I take his hands, put them into various arbitrary positions, tell him he cannot change these positions, and leave him so. Stroking the thumb and finger, I tell him he will find them in a normal state when he wakes up. I leave him in this state of cataleptic sleep or trance for two, five or ten minutes, then touch him and tell him, "That is all," and he returns to consciousness. The patient tells you he was asleep, and yet it was a different kind of sleep: that he heard my voice, but nothing else, and that he felt that he had to do whatever I said, etc.

*Note.*—I subsequently exhibited this patient before the West End Medical Society, New York City, perfectly well in every respect. Six seances occurred altogether.

105 West Seventy-third Street.

## DRY SUPERHEATED AIR IN THE TREATMENT OF SEPTIC INFECTION.*

BY CLARENCE EDWARD SKINNER, M.D., LL.D.,

OF NEW HAVEN, CONN.;

PROFESSOR OF THERMOTHERAPY, AND PRESIDENT OF THE FACULTY AT THE NEW YORK SCHOOL OF PHYSICAL THERAPEUTICS; EDITOR OF THE DEPARTMENT OF THERMOTHERAPY IN THE JOURNAL OF ADVANCED THERAPEUTICS; PHYSICIAN IN CHARGE OF THE NEW-HOPE PRIVATE SANITARIUM, NEW HAVEN, CONN.

ONE of the most dreaded of the pathological states which we encounter with a moderate degree of frequency to-day is septic infection. It is also one of those conditions, which, when fully developed, offers very meager prospects for successful management under ordinary methods of treatment. About the only effective management has been to prevent the accident from occurring, and honor will never cease to be paid to Sir Joseph Lister and those who have followed him in developing the technic of antisepsis and asepsis to the wonderful degree of thoroughness and efficiency, which to-day enables our surgical con-

* Read before the Clinical Society of the New York School of Physical Therapeutics.

freres to accomplish curative feats that would have been characterized as nothing short of absolute magic by the practitioner of fifty years ago.

When septic infection has once gained a foothold in the human system, however, neither antisepsis nor anything else has offered us much in the way of power to extinguish the conflagration, and we have had to go back to the first principles of therapeusis, merely keeping the patient's general condition as good as possible, and hoping that his constitutional vitality would enable him to overcome the invasion. Sometimes when the infection is confined to a limb we can cure the patient by amputating the infected member, and although this is a most distressing alternative for the patient, yet it is better than death, and he will usually consent. But in how large a proportion of cases do we see the infection reappear in the stump two or three days after the operation, to impress us anew with a realization of our helplessness in the presence of well-established septic infection? Therefore, any remedial measure which promises to be helpful in the battle with so intractable a condition as this, deserves consideration and study, and dry hot air promises to exhibit this power in an eminent degree.

When a new therapeutical agent is brought to our attention the first question that naturally arises is "What will it do?" and in considering the therapeutical application of dry hot air with reference to septic infection we find it convenient to divide the cases into three classes: (1) Those in which the infection has taken place in a limb and has not yet invaded the lymphatics of the joint connecting the member with the trunk, and which are nearly always early cases: (2) those in which the lymphatics of the trunk have also become involved, but where the original focus of infection has not yet become so profoundly effected as to demand removal: and (3) those in which the lymphatics of the trunk are involved and the tissues originally invaded are so hopelessly diseased as to demand immediate operative interference. The two last-mentioned classes nearly always exhibit a profound systemic toxemia, as will also an occasional case belonging in the first-mentioned category.

Among thermotherapists the beneficial influence of dry hot air upon the progress of cases belonging in the first-mentioned class of infections is so well established as only to need a mention in order to be appreciated, but as the vast majority of you are not thermotherapists, and as very few of you are at all familiar with the agent in any of its therapeutical or clinical aspects, I will cite briefly the following case, as illustrative of its power in this situation.

*Case.*—Mrs. F. D. K., twenty-four years old, punctured the middle finger of her right hand with a fork April 16, 1901. The wound showed evidences of infection the next day which rapidly increased, involving the hand and wrist until April 19, upon which day she consulted me about the matter. At this time, the finger, hand and wrist were badly swollen. Red streaks ran up the forearm nearly to the elbow and the lymphatics of the elbow were palpably enlarged. Constant and severe pain was present in the arm throughout its extent. She had not slept for thirty-six hours. Pulse 100 per minute, temperature 103° F. She was given a local hot-air treatment which included the hand, forearm, and up to a point two inches above the elbow, at 400° F. for an hour. The pain was entirely relieved during the treatment and she was told to report again in the evening for another application, which she did. At this time there was no apparent change in the local condition. No extension of the process had taken place, neither was there any evident diminution in the areas involved. The relief from pain due to the first treatment lasted five hours. At this time it was again quite severe. She was given another local application of the same character as the first which again relieved the pain completely. She was directed to come on the following morning for another seance.

She appeared according to appointment. She had slept nearly all night, the swelling had decreased 50 per cent., redness had disappeared everywhere except in the immediate vicinity of the original injury, and the enlargement of the glands at the elbow had decreased in a marked degree. The member was painful only on movement and manipulation. Pulse was 80 per minute. Temperature 99.5° F. She received eight treatments during the next five days. The pain did not return after the treatment on the morning of April 20. The swelling of the hand and forearm and the enlargement of the glands at the elbow decreased steadily and rapidly and on April 25, or six days after the first hot air treatment, she was discharged without a trace of the trouble remaining.

In cases of the second class the therapeutic problem becomes considerably more complicated, but the clinical phenomena are scarcely less striking, and the following case exemplifies very well the results usually obtainable here.

*Case.*—Mr. G. P. H., thirty-two years old, was brought to the sanitarium March 2, 1901, by Dr. A. S. Cheney of New Haven. Four days previously he had cut his hand with a dirty jack-knife. The usual evidences of infection duly appeared, and when he entered he was in a condition of profound prostration with a temperature of 103.4° F.; respiration 28, but the pulse was only 86. Hand and arm were considerably swollen. Lymphatic glands about the elbow and in the axilla were irregularly enlarged, those in the latter situation to about the size apparently of an English walnut. He was in constant severe pain. The presence of deeply located suppuration seemed probable but was not positively demonstrable. He had been brought in with the intention of operating the next day. It was finally decided, however, to treat him with hot air first, holding operative interference in reserve.

At noon of the day following his admission he was given a body hot-air treatment at 340° F. Perspiration was profuse, the pain was relieved

entirely before the conclusion of the treatment, and he had a quiet, refreshing sleep after he had been removed to his bed. The evening temperature was 102.5° F. as against 103.4° F. of the previous day.

Next morning at 8 o'clock his temperature was 99.9° F. and pulse 84. The patient had slept several hours during the night. The pain had not returned to any great degree, and the prostration and nervous symptoms were greatly lessened. The swelling in the hand and arm was less, as was also the enlargement of the glands in the axilla. He was given another body treatment at noon at 350° F. His temperature was 101.8° F., pulse 80, as against 102.5° F. and 94 respectively the preceding evening.

Treatment was administered again late in the afternoon. Morning temperature the next day was 99° F., pulse 78. Patient had slept at intervals during the night and during the day, resting quietly. That evening his temperature was 100.4° F., pulse 76. Pain and swelling had entirely gone out of the arm but the axillary enlargement persisted as did also a considerable amount of pain in this region.

The following day, March 7, his morning temperature was 99.4° F., pulse 76. In the afternoon he was given a body hot-air treatment at 350° F. and the next day his temperature in the morning was 99° F., pulse 70. In the evening the temperature rose to 100.6° F., with the pulse averaging 88.

At this time palpation of the axillary enlargement demonstrated the presence of pus and it was decided to open the axilla the next day, which was done at four o'clock in the afternoon, Dr. Cheney operating. Upon incision, a large quantity of fluid pus was evacuated and a pocket was discovered running up under the clavicle for a distance of about three inches, of a diameter sufficient to admit of exploration with the forefinger. This cavity was lined with an enormously thickened pyogenic membrane, and *no glands outside of it were involved in the infective process.* It will be observed that this is a very different picture from that usually encountered under these conditions, where the contents of the abscess cavity consist of pus with a plentiful admixture of cheesy detritus which it is not at all easy to remove in a thorough manner, and where gland after gland is found to be infected, necessitating a vast amount of dissection in order that the extirpation shall be complete.

The pyogenic membrane was curetted out and the subsequent progress of the case toward recovery was rapid, satisfactory, and uneventful. On March 13, the body temperature returned permanently to the normal point and he was discharged on March 23, just three weeks after his admission, entirely recovered from an attack of septic infection which was very evidently seriously threatening his life when he entered.

This case illustrates the necessity of combining operative interference with dry hot-air treatments in those cases where such structures as lymphatic glands have become diseased to such an extent that disintegration is inevitable and pus accumulations are present. The immediate improvement in the patient's general condition after the first hot-air treatment together with the strenuous localization of the inflammatory process in the axilla, illustrate the powerful influence of body hot-air treatments in lessening general systemic toxemia, and in preventing the spread of the infection from structure to structure through its power of increasing the constitutional resistance of the cells composing the threatened areas.

The shocking railroad accident, which occurred in the Park Avenue railroad tunnel about a year ago, furnished an illustration upon the person of one of the victims, of what thermotherapy can do in infections belonging in the third category.

*Case.*—Mr. A. W. A., aged fifty-one years, was admitted to the New York Hospital on the morning of Jan. 8, 1902, with a traumatic amputation of the left foot at the ankle. The crushed member was attached to the leg merely by the lacerated posterior tendons. Patient of course was suffering considerably from shock. Amputation of the lower third of the leg was done by Dr. Francis Marcoe that afternoon. Septic infection, however, declared itself three days after the injury. On January 12 it was noticed that the knee was swollen; on January 15 pus began to discharge from the wound, and in spite of the utmost care the condition increased in gravity until January 23, fifteen days after the original injury. At this time the leg up to the knee and somewhat above this joint was enormously swollen, the tissues of the stump were sloughing in places and the patient's general condition was one of extreme prostration. In short, he presented a typical picture of the severest form of blood-poisoning, except that streptococci had not been found in the blood.

It was decided to amputate the infected member above the knee as a forlorn hope. This was done by Dr. Frank Hartley on the evening of January 23, at the middle of the thigh. He rallied very well from the operation and the next morning was given a body hot-air treatment. During the time intervening between January 24, the day of the second operation, and March 8, the day of his discharge from the hospital, the patient received 13 body treatments, the greater number of which, of course, were given during the two weeks immediately succeeding the amputation of the thigh. His general condition began to show slight evidences of benefit at once in the way of increased comfort, ability to sleep, and improvement in the vital signs, and he continued to gain slowly but steadily, until by February 5 his improvement had become so manifest as to justify a prognosis of recovery with a moderate degree of certainty. From this date on, his improvement was entirely satisfactory, and to-day his general condition is better than it has ever been in his life before, and he weighs as much

within one pound without his leg as he ever did with it.

In order to indicate the gravity of the case I will say here that it was the unanimous opinion of the physicians who saw him that neither the operation nor any ordinary therapeutical measure would save the patient's life. The fact also that slight evidences of tissue disintegration appeared in the wound three days after the second operation, is indicative of the fact that the operation and therapeutical measures other than hot air would not have sufficed to secure a successful termination.

Now, as it has been objected that the beneficial results of hot-air therapy are coincidental and not due to powers inherent in the agent itself, I will say here that this might constitute a plausible theory if those results had been observed in only a few cases, but when they are noted in case after case the conviction finally becomes inevitable that the remedy is the responsible factor, and such has been the course of events in connection with the remedy under consideration.

As far as I know hot air has not been used in a case of septic infection in which streptococci have been found in the blood, but its physiological action indicates that it will be of great assistance in even this ordinarily hopeless condition. Cases of puerperal sepsis have also not as yet been subjected to its influence. There is apparently no reason why we should not be able to get good results in this condition.

The cases recently reported by Dr. Barrows, of New York City, in which streptococci were found in the blood and which recovered under the use of intravenous injections of formalin, suggest most attractive possibilities in the treatment of this grave form of sepsis for the future, and it is most sincerely to be hoped that future experience with the intravenous injections of formalin will justify the expectations which have been raised by these cases.

So much for clinical results. The next question presenting itself for consideration would be "How does the agent produce these effects? What is the physiological modus operandi of the influence which has been observed?" To answer this query, we shall have first to ascertain the physiological action of treatments with dry superheated air, and then to consider the pathology of septic infection with reference thereto.

It will be observed that two varieties of hot-air applications were employed in the cases just cited; one where only the part affected was treated and which is denominated the "local treatment," and the other where the greater portion of the body surface was subjected to influence, and which is denominated the "general" or "body treatment." Although the physiological actions of these applications differ from each other chiefly, as far as septic infection is concerned, in degree rather than in kind, yet we shall find it instructive to consider them separately in connection with the cases just cited, and will give our attention first to the local treatment.

This therapeutical measure affects physiological function in two ways; first, by a direct stimulation of cell metabolism in the part treated due to the raising of its temperature en masse; and second by a reflex acceleration of cell nutrition set up by the stimulating influence of the heat upon the numerous nerve endings in the skin.

It is, of course, not possible to raise the temperature en masse of one portion of the body very much higher than that of another portion, but by placing the bulb of a clinical thermometer at the bottom of a deep sinus and then applying a hot-air treatment, it has been demonstrated that an increase of several degrees Fahrenheit can be induced. This is enough to accelerate oxidation processes very perceptibly, and also to inhibit appreciably the development of most of the common pathogenic micro-organisms.

It has been suggested that the germs in these cases were directly *destroyed* by the heat. This view, however, is improbable, and there is no experimental or clinical evidence available indicating that it is possible to raise the temperature of any portion of the body sufficiently high to produce this result.

Through the reflex influence is obtained an emphatic local hyperemia, which, together with the stimulation of the trophic nerve supply of the part treated, results in greatly increased local nutrition, whereby the vigor of the normal cell resistance to germ invasion is accentuated.

Copious perspiration appears upon the region treated, and in greater or less degree upon the rest of the body, whereby the general circulation is relieved from a certain proportion of the toxin which is impregnating the body fluids.

To the influence upon the circulatory function of the part whereby stasis is relieved, is probably due the powerful influence of dry hot-air treatments in relieving pain and swelling.

The physiological action of the body treatment is predominantly reflex through the spinal sympathetic, the area of skin affected being so great that the capillary circulation is able to dissipate the heat before it penetrates deeply enough to exert its action directly to any great extent, therein differing from the local application.

Microscopical and chemical examinations have demonstrated that the following phenomena are susceptible of immediate induction by the body hot-air treatment. (1) If hyperleucocytosis is not already present the number of white blood corpuscles is increased in different cases from 15 to 50 per cent. If it *is* present, the increase is usually not so great, or it may be entirely nil. (2) The red blood cells are increased from 10 to 20 per cent. (3) The quantity of urine passed in the twenty-four hours succeeding the treatment is usually increased from 25 to 100 per cent. over the quantity passed in the twenty-four hours preceding. In a few instances, however, a decrease in the quantity has been observed. (4) The quantity of urea excreted in the twenty-four hours succeeding the treatment is increased from

15 to 60 per cent. over that excreted in the twenty-four hours previous. These effects persist, with decreasing intensity, for from four to forty-eight hours and sometimes longer.

The general phenomena induced by the body application are as follow: The mouth temperature rises from 1 to 5° F., according to the length and intensity of the application, and the susceptibility to stimulation of the individual patient's deep nerve centers. The pulse is accelerated from 30 to 50 beats per minute and is markedly increased in volume. If it was weak before treatment it now becomes strong. If the application is continued too long it loses its volume and strength, becoming rapid, small and soft. The respiration deepens and the rate increases 5 to 10 cycles per minute, but this modification is not accompanied by any oppression—rather the reverse, in fact. The capillary areas become injected, but this phenomenon is not so marked in the regions actually in contact with the heat as with the local treatment. The fact that the capillaries of the face, which is not subjected to the heat, share this general distention even when constantly under the influence of the breeze from an electric fan, demonstrates the profundity of the reflex obtained. The patient reeks with perspiration, the acidity of which is markedly increased over that normally exhibited.

By this profound stimulation of the deep trophic centers we secure first, a more rapid and complete oxidation of effete materials which are clogging metabolic processes, figuratively speaking, into normal excretory products—urea for the kidneys, $CO_2$ for the lungs etc.,—which are then easily disposed of by the appropriate organs: and second, a rapid production of more vigorous and healthier cell elements which are much better able than their predecessors to resist toxemia and microbic invasion. Such being the physiological effect upon the human organism of dry hot-air applications, let us glance for a moment at the pathological conditions obtaining in septic infection, and see whether or not they are such as would logically indicate the induction of these influences. The primary etiological factor consists of the lodgment in the lymph spaces of pathogenic micro-organisms. After this event has occurred, one of two things will happen: (1) What we will denominate the patient's constitutional resistive power, may be intense enough to enable the cells composing the invaded tissue to destroy the infective organisms, in which case nothing further will be heard from them. (2) The patient's normal constitutional vitality may be lowered from some cause, or the resisting power of the tissues attacked may be weakened, as by impairment of the trophic nervous control from injury or shock, for instance, in which contingency the invading organisms find a pabulum suitable for their development, and they multiply with exceeding rapidity, spreading colony after colony into the numerous ramifications of the lymphatic system, until finally millions of noxious toxin producers are vomiting their paralyzing venom upon structures whose trophic processes are more and more overwhelmed until beyond the possibility of spontaneous redemption, thus rendering larger and larger areas of tissue a favorable soil for their further propagation. These poisonous emanations, together with the ptomains, resulting from tissue disintegration, are taken up by the general blood circulation and brought into contact thereby with all the nerve centers and other tissues of the body, whence results the evil clinical picture so harassingly familiar to most of us, as "blood poisoning."

Two important points to be borne in mind in this connection are, first, that when the normal resisting power of a tissue is unimpaired it is probable that it is capable of overcoming any ordinary microbic invasion: and second, that most of the common pathogenic germs require for their propagation that the conditions most favorable to their development as regards the temperature of their environment, etc., be maintained with a moderate degree of uniformity. These conditions exist very nearly to the point of perfection in the living tissues of the human body, and any influence which alters them to any extent would tend to inhibit the growth of the germs in proportion as the alteration was profound. Now, when a local hot-air application is made to a part exhibiting the evidences of septic infection, what is the sequence of events inaugurated thereby? (1) the reflex stimulation of the vaso-motor tracts through thermic irritation of the nerve endings in the skin, relieves the fluid stasis in the part, thereby lessening the pain: (2) the nutrition and cell vitality of the part are augmented by reflex stimulation of the trophic nerve supply through the same channels: (3) the raising of the temperature of the part, en masse, disturbs one of the most important conditions, which it is essential should be maintained unimpaired, if the propagation of the micro-organisms is to reach its fullest development: (as we have seen the living tissues of the human body, when exempt from modifying influences, constitute an ideal culture medium): and (4) the integumental emunctories are stimulated to greatly increased functionation. Now the lessening of the pain quiets the patient's nervous system in direct proportion as the relief is complete, thereby conserving his nervous energy, and the relief of stasis insures a plentiful supply of raw material in the form of an augmented blood circulation, out of which new cells may be built up to take the place of the exhausted, worn-out elements; the augmented trophic impulses result in advantage being taken of this increased supply of raw material for the rapid formation of cells possessing a heightened vitality, whereby the resisting power of the tissue is at once greatly increased: the raising of the temperature of the part, en masse, exercises an inhibitory influence upon the development of the colonies of micro-organisms whereby the virulence and quantity of the toxins emanating therefrom are reduced in direct proportion as the inhibition is profound; and the

enormously increased functionation of the sweat glands removes directly, from the parts most profoundly influenced by the intoxication, a certain proportion of the noxious substances which had previously been devitalizing fresh areas of tissue and passing into the general circulation. What is the result? Instead of the destructive process spreading farther and farther into the sound tissues, we find that the cells at the periphery of the infection, which were just beginning to feel the debilitating influences of the approaching destruction, are regenerated and carry on their reconstructive functions with a normal, or perhaps even an abnormal, degree of activity and efficiency, pushing the lines of healthy tissue farther and farther into the diseased areas, until finally the pathological mass is entirely replaced by healthy tissue and the patient has recovered, frequently *without even a slough*. When a collection of pus is present, however, it is necessary that it be evacuated, neither hot air nor any other measure with which I am acquainted being capable of producing absorption. But even when pus is present hot air will strenuously localize the inflammatory action very closely to the abscess cavity, when a stroke of the knife will end the trouble once and forever.

I wish to refer here, briefly, to statements which I have seen that local hot-air applications to localized infections of any sort were dangerous, and very likely to transform a local into a general pathological condition. I have never heard a logical defense of this statement, and I have never heard of an authentic case where there was any satisfactory evidence that such a result was properly attributable to hot air. Further, in the many thousands of such treatments which I have administered myself, and have had administered under my supervision to such cases, I have never, in a single instance, seen the slightest reason to consider that hot air had been guilty of precipitating such a disaster, and I am free to state my entire disbelief in the existence of any cause for apprehension in this respect.

With cases belonging in the second and third categories, the physiological effect of the local treatment will not usually be sufficient to produce a cure, because in these cases foci of infection have appeared in parts so situated that the maximum influence of the local treatment cannot be brought to bear directly upon them. Under these conditions it becomes necessary to call up all our patient's reserve forces, to stir his vital resistance against the invading organisms to its profoundest depths, and the body hot-air treatment enters the therapeutical problem.

With this application we cannot invoke the directly inhibitive influence upon germ development due to the raising of the temperature of the part, that is obtainable with the local treatment. As we have seen when considering the physiological action of the body treatment, the normal mouth temperature is rarely increased beyond 3° F.; this is not enough to appreciably retard the growth of the streptococcus. Indeed, patients very frequently exhibit elevation of temperature to this extent when they enter the apparatus. The greater beneficial power of the body treatment consists in, first, the greater proportion of systemic toxemia which is eliminated through the increased functionation of the skin, kidneys, and lungs, whereby the vital processes are more efficiently relieved of impairment and depression; and second, its gratifying influence in stimulating to renewed vigor of function the deep spinal and sympathetic nerve centers that control tissue reconstruction, and which have been overwhelmed to a greater or less extent by toxin accumulation in the general circulation.

Usually the first indication that the former has taken place, is a lessening of the nervous erythism which becomes manifest immediately after, and sometimes before the conclusion of the first treatment, when the patient frequently falls into a refreshing sleep lasting from one to several hours.

The augmented functional vigor of the deep spinal sympathetic nerve centers is evidenced before the patient leaves the apparatus by the improved character of the pulse, and within twenty-four hours usually, the reinvigoration of the trophic functions is manifested by a marked lessening and sharp localization of the local inflammatory phenomena.

Lack of time forbids my entering largely into the subject of technic, but I wish to say just a word in reference thereto, as the difference between a skilful, thorough application of the agent and the reverse, will not infrequently constitute the difference between success and failure in clinical results. The most prevalent error in the popular conception of the modus operandi of the curative power of hot air, is that it produces its effect merely through the induction of integumental hyperemia, and toxin elimination as represented by the induction of profuse perspiration. This has led to applying the agent at temperatures only sufficiently high to produce sweating, that is from 200° F. to 250° F. By this means elimination has been secured, and very effective elimination, too, but that is all. Now to obtain the best and the permanent curative influences of dry hot air, we must not only induce elimination, but we must also supplement and perpetuate as far as possible the advantage dependent thereon, by augmenting the trophic reconstructive functions whereby we increase the patient's constitutional resistance, and effective stimulation of these processes is not possible unless the higher temperatures, from 300° to 400° F. are used.

One more important point in connection with the technic of the body treatment is that no hard and fast rule as regards the duration of the application or the intensity of the heat employed can be laid down to govern all cases. The susceptibility to thermic stimulation of the nerve centers of different individuals varies greatly, and each must be treated according to the physiological phenomena induced in his particular case at each treatment. Overstimulation is not difficult of induction with many patients, and this

would be nearly if not quite as bad as an inefficient application. In non-febrile cases, and those exhibiting only a low degree of febrile action, it is usually an indication that sufficient influence has been induced when the mouth temperature has been increased 2° F. above the normal, or when the pulse has been accelerated to 120 or 130 beats per minute. In septic infection, however, an abnormally high body temperature and an accelerated pulse-rate usually obtain when the patient enters the apparatus, hence these modifications of the vital phenomena cannot be entirely relied upon here as guides to treatment duration and intensity. The general effect upon the system at large must be consulted, and the instinct which is the result of experience is invaluable. As a rule, however, it may be said that the pulse should not be accelerated beyond 140 beats per minute, and that nausea, giddiness, faintness and other evidences of overstimulation should be carefully avoided.

The third and last phase of the subject which we will consider, relates to the employment of other therapeutical measures in conjunction with hot air. Can better clinical results be obtained by combining other things with this agent than by relying upon it alone? The question may be unhesitatingly answered in the affirmative, and in some diseases other than the one under consideration, very emphatically in the affirmative. In septic infection, however, the other measures which will enter the therapeutical problem are few, and consist chiefly in judicious regulation of the diet, proper regulation of the excretory function of the bowels, preferably by calomel and salines, appropriate surgical dressings where there is an open wound, and the early evacuation of pus and removal of sloughing tissues wherever and whenever they are in evidence. Pain relieving drugs and stimulants will very rarely be required when skilfully applied hot-air treatments are obtainable. Sometimes open surfaces will exhibit sluggish reparative action and refuse to heal, and here the application of the negative pole of the galvanic battery, employing a bare metal electrode and three to five milliampères of current will render most excellent service. Care must be exercised not to use enough current to cauterize, however; the beneficial influence is obtained through electrolytic not destructive action, and the induction of the latter will sometimes retard the curative process. Aside from this, electricity will rarely need to be considered in this affection, when hot air is obtainable.

In conclusion, permit me to say that, although dry hot air in the treatment of septic infection is a "good thing," yet it is not invariably a "dead sure thing." Side-lights, in the form of individual idiosyncrasy on the part of the patient, or variations in the inherent malignancy of different instances of even the same types of infection, will sometimes flash across the scene with an intensity sufficient to embarrass most seriously the exercise of a satisfactory influence on the part of any curative agent. It will alone and unaided, cure many cases; others will require all the remedial resources at our command; and in still others all that we have will not suffice to produce a cure. It is simply a rational curative measure exhibiting a known and constant physiological action, and which, either alone or in combination with other agents manifests the capacity to increase vastly our power to overcome this condition in the majority of cases. It is, therefore, entitled to a prominent position in our armamentarium.

---

## THE SANATORIUM TREATMENT OF TUBERCULOSIS.

BY HERBERT MAXON KING, M.D.,
OF LIBERTY, N. Y.;
PHYSICIAN IN CHARGE, LOOMIS SANATORIUM, LIBERTY, N. Y.

(Concluded from Page 19.)

In describing more specifically the treatment of the individual patient in the institution, as will naturally be inferred, I have chief reference to the methods as employed at the Loomis Sanatorium.

The first procedure necessary upon the admission of a patient is to ascertain, with as much accuracy as possible, his exact condition, not only with reference to the respiratory organs but to the constitutional status in general. For this purpose the patient is placed in the infirmary, and, unless otherwise indicated, in bed. In taking the history and making the examination it has proved most satisfactory to follow a definite plan of arranging and charting the data with as much regularity of system as is consistent with freedom of questioning. I have here the charts of two hypothetical cases which will illustrate better than I can describe it, the order of procedure at the Loomis Sanatorium. Part I is a general summary and cannot be completely filled out until the patient is discharged: it serves to enable one at a glance to gather all important facts with regard to the individual case and from which the annual reports may be most conveniently made up. Part II contains the family and personal history. In this connection it has proved of inestimable advantage to go very fully into the past life, habits and environment of the patient in order to lay out more appropriately the special course to be followed in the given case, besides greatly facilitating future individualization of treatment. Part III goes a little more explicitly into the history of the present illness with the symptomatology below. I would call your attention here chiefly to the subjects: "History of Infection," "First Presumable Evidence of Disease" and "First Demonstrable Evidence of Disease." The careful following out of which has often thrown unexpected and valuable light upon a case.

Part IV contains the first and most important results of physical examination and as you can see is, so far as the chest is concerned, recorded graphically.

Part V is a continuation of physical examination.

Part VI is the temperature, pulse and respiration chart, and gives an eight weeks' record for each chart. Temperature, which is such an important guide in tuberculosis, is taken in the mouth, axilla and rectum until discrepancies can be satisfactorily eliminated, after which mouth temperature alone suffices until some change in régime is prescribed as, for instance, increased exercise, when for a few days rectal temperature is taken as a control.

Part VII serves to record the weights and sputum examinations during residence. In this connection I may say that patients are weighed every fortnight only, always before the mid-day meal and always by net weight.

Part VIII the urinalysis and blood examinations.

Part IX is left blank for recording monthly synopses of treatment and régime employed and the noting of phenomena in a case not provided for in the foregoing sheets.

It often becomes necessary to make a more or less exhaustive examination of the stomach in certain types of tuberculous patients, and the form for such, as you see it attached to these hypothetical histories, is taken from that employed at the University of Michigan Hospital by Prof. Dock.

By means of these charts a very full and clear contemporary history of the case is constantly available upon which to base treatment from time to time and finally from which to draw accurate statistics. From these data gained upon admission the case is classified according to the condition found. Various nomenclatures and methods of classification are employed in different sanatoria; probably Dr. Trudeau's plan is simplest and most commonly used. He divides his cases into incipient, moderately advanced and far advanced. For purposes of future study, however, and with the hope of avoiding some of the pitfalls of statistics I have adopted a little more explicit classification at the Loomis Sanatorium. Like Dr. Trudeau and others, I make three divisions but subdivide each group, thus making six instead of three classes into which a given case may be placed as follows:

Early { mild symptoms / acute symptoms

Advanced { with favorable symptoms / with unfavorable symptoms

Long Standing { fibrosis predominating / ulceration predominating

Upon admission to the sanatorium the patient is at once supplied with the proper receptacle for expectoration and a small printed folder embodying general information and the rules governing patients in the institution. These are worded in the simplest and most intelligible manner; but to guard against misinterpretation or carelessness the head nurse goes over salient points with the patient.

The sputum cup used in the infirmary, or during the period of rest is one, the receiver of which is made of paper and can be burned. Later on, when the patient becomes an ambulant case, a pocket flask is much to be preferred for obvious reasons, and for this purpose I prefer the modification of the Detweiller flask the modification consisting merely in substituting an aluminum for a glass body. These flasks are cleansed and sterilized by a nurse each day in a manner effective and safe, the details of which are unnecessary to consider.

The patient is detained at the infirmary then, until his condition warrants removal to a room in one of the cottages. This is ordinarily a matter of but a day or two. He is still kept however under close supervision, and takes no other exercise than is occasioned by coming to his meals three times daily, extra diets being supplied him at his cottage. If he is much below weight, this life of enforced rest must be kept up until his weight approaches the normal average, unless his gain is unduly rapid, in which case mild exercise is prescribed but always under the most rigid supervision. During this period of enforced rest, which is invariably maintained for the first few weeks of his residence, the patient occupies a reclining chair on the veranda sheltered from the severities of the weather, clad and wrapped with a view to his comfort and, of course, according to the season of the year, for from six to ten hours a day. At night he sleeps with windows wide open and in winter between flannel blankets. Half an hour before he rises in the morning an attendant closes the windows and the room is sufficiently warm to permit of comfortable bathing and dressing. During the early part of this rest period his digestive system receives the attention which it usually demands. Mild purgation is ordinarily required following which a light diet for a few days generally serves to prepare the stomach for the increased work which is to follow. As a routine practice this is very essential.

He is at this time permitted to read, play chess or checkers, or by other means to occupy his mind, provided pulse and temperature be not accelerated thereby. For the purpose of using his arms conveniently in the cold weather and at the same time to secure sufficient protection while at rest there are many devices in the way of specially adapted wraps, sleeping bags and the like. I have tried various of them but the modified steamer-rug (devised and manufactured by the Kenwood Rug Co., of Albany) has given the greatest satisfaction, as it is made with a detachable hood and of a specially prepared wool which, without being in the least cumbersome, I have found to be sufficiently warm for the coldest weather, and very convenient for the purposes desired. This article has the additional advantage of being considerably less expensive than most such special devices.

At the end of a period varying from a fortnight to a number of months, according to circumstances, the patient is ready to be placed

upon exercise. This period is determined by the condition of the pulse, temperature and weight. An average pulse rate of 100 or more while the patient is at rest would contraindicate exercise, as would a morning temperature (per rectum) above 99° F. or an afternoon rise exceeding 100° F. While a failure to increase a remarkably subnormal weight would also be a contraindication.

The first exercise should be prescribed with caution and treated as an experiment. It should consist ordinarily of a measured walk on a level and should not exceed a few hundred yards. If this be found not to excite temperature or materially increase rate of respiration, it may in a few days be extended gradually. Mild calisthenics may then profitably be introduced, limited to those exercises which tend to develop the mobility of the chest. I prefer the three sets of simple movements recommended by Knopf[6] which seem to answer the purpose very well. After this, may come hill-climbing, but always with the utmost caution at first. On the sanatorium grounds should be a series of graded paths of known incline with rest stations at frequent intervals so, that this exercise may at first, at least, be prescribed with exactness. Gradually as the disease approaches arrest and rational symptoms disappear, the close personal vigilance may be relaxed but there should never come a time during the course of his residence in the sanatorium when the patient is without that watchful medical supervision which is the keynote of sanatorium treatment.

He may now extend his exercise considerably with advantage and in those sanatoria which are intended for the benefit of the working classes, this exercise may be diverted into useful and profitable lines. For instance at the Loomis Sanatorium Annex, late last fall, I introduced the plan of giving suitable cases among the male patients the opportunity to do light work on the sanatorium farm under the direction of a skilled farmer. They were carefully watched during the experiment, and while the time was too short to allow of any conclusions being drawn, none but good results followed. We shall repeat the experiment during the next summer and if successful it will be suggestive of a plan to make the consumptive convalescent of the poorer class self-supporting during treatment.

Another experiment with regard to the value of increased exercise in convalescents from phthisis was carried out at the Sanatorium Annex during the autumn. Twenty patients all with quiescent lesions, without rise in temperature and up to, or a little above, normal weight, were selected and divided into two classes of ten patients each, known as "Class A" and "Class B" respectively. In "Class A" there were five men and five women (one more male patient entered this class, but together with two others was obliged to leave the sanatorium before the completion of the experiment).

In Class B there were six men and four women. The experiment consisted in placing Class A on greatly increased exercise (hill climbing) for a period of two weeks, during which time Class B was upon a régime of enforced rest. The following two weeks the conditions were exactly reversed. Class B taking the increased exercise and Class A the enforced rest.

Observations were made of pulse and temperature for one week prior to the test, during the test and for a week following the test. Changes in weight were recorded under the various conditions as were the effects produced upon cough and expectoration.

Following are the tables showing in detail the records of the two classes and the summary:

CLASS A.—PERIOD OF INCREASED EXERCISE.

| Case | Period of observation 1902 | Weekly Average T. and P. | | | | | | Weight after test | |
|---|---|---|---|---|---|---|---|---|---|
| | | Previous to test | | During test | | After test | | gain lbs. | loss lbs. |

From the latter it will be seen that the average maximum weekly temperature actually fell during and following the test in both classes, while even the pulse was not materially affected. With the weight there was a small balance in favor of the period of enforced rest in both classes, but it must be remembered in

this connection that most of these patients were above normal weight before the experiment was undertaken. In Class A during the period of increased exercise there was a total gain in weight of 14⅞ pounds and a total loss of 2¼ pounds, while during subsequent period of enforced rest there was a total gain of 16½ pounds and a loss of one-half pound. In Class B during the period of exercise there was a total gain of 13⅛ pounds and a loss of two pounds. While during the antecedent period of rest there was a total gain of 26 pounds and a loss of one pound. The effects of the experiment upon the symptoms may be gathered from the tables. It is worthy of remark, however, that in every instance the patients *felt better* during the period of increased exercise.

It is hardly necessary to add that all patients on exercise should be advised to rest, and in cases of recent activity to recline both before and after meals particularly with respect to the hearty meal of the day. This is an invariable rule in the German and Swiss sanatoria with which I am familiar and I believe it to be a good one.

The diet of the tuberculous patient is, of course, a matter of vital importance. There can be no hard and fast rules, however, applying to all cases alike. In a general way it will be determined by the amount of weight lost in a given case and the type of fever present. In the acute stage of the disease a heavy proteid diet would be as much out of place as if the case were one of typhoid fever. During this period liquid foods should predominate, but as the temperature subsides and the acute symptoms disappear, best results undoubtedly follow a return to the more normal relations of the various elements of a mixed diet, with this exception that the proteids should be largely increased both relatively and actually.

With the ordinary patient, unless weight is far below normal, three hearty meals per day suffice to produce a gain of from one to five pounds per week during this life in the open air until the individual average is approached, when gain will naturally be less rapid.

In cases where response to treatment is sluggish, the regular meals are supplemented by additional diets at stated intervals, consisting usually of milk, eggs, broths, cocoa, etc., prepared in various ways according to individual tastes. Forcing diet beyond the point of comfort is, in my experience, an unwarrantable practice and is almost surely to be followed by anorexia dyspepsia, nausea, diarrhea and other abdominal symptoms. On the other hand if the patient merely has a disinclination for food without evidence of tuberculous lesion in the digestive tract, "gavage" may be practised for a time, and as you know with astonishingly good results in certain cases. There is this advantage in "forced feeding," the stomach which has heretofore revolted at any considerable amount of food ingested in the ordinary way, accepts the introduction of large amounts via the tube, and in a surprisingly short time the patient is enabled to take his food by the natural process.

With regard to the diet of quiescent cases, I have ascertained by experiment at the Loomis Sanatorium Annex that which gave the most satisfactory results by placing six selected patients at a table by themselves and carefully weighing all food consumed for a period of one week and averaging the amounts of each constituent per day per patient. The results of my experiment correspond very closely to those obtained by Bardswell, Goodbody and Chapman in the sanatorium wards of Brompton Hospital.[7]

The following table shows the comparison between the diets at Brompton and the Loomis Sanatorium Annex:

| | Loomis Sanatorium Annex. | Brompton Hospital. |
|---|---|---|
| Soups | 5.5 ounces | 0. ounces |
| Cereal | 3. " | 0. " |
| Meat and Eggs | 9. " | 8. " |
| Bacon | 0. " | 2. " |
| Vegetables | 12. " | 6. " |
| Bread | 8. " | 7. " |
| Butter | 1. " | 3. " |
| Milk | 62. " | 48. " |
| Cocoa | 4. " | 0. " |
| Sugar | 1.5 " | 1. " |
| Dessert | 2.5 " | 3. " |
| Fruit | 6.2 " | 0. " |

During this week the average gain in weight per patient at the Loomis Sanatorium Annex was 1.3 pounds. It will be seen that the diet at the Loomis Sanatorium was somewhat larger than that at Brompton, but in both cases they were found to be eminently satisfactory.

A word must be said on the employment of hydrotherapeutics in sanatorium treatment of this class of invalids. It has been proved very conclusively that tubbing for the reduction of temperature in septic cases of tuberculosis not only is of little avail but is absolutely disastrous, and in the sense that cold baths are valuable in typhoid, they have no place in phthisis therapeutics. On the other hand, tepid sponging or employment of the wet pack during the hyperpyrexia of acute or advanced phthisis is to be recommended and in infirmary practice at the Loomis Sanatorium has proved the only useful adjunct to absolute rest and proper feeding in controlling the fever.

Alternate hot and cold douching, under pressure, the shower, spray and other refinements of "water treatment" have a definite and considerable value in quiescent cases when elimination is deficient, and the appetite and digestion imperfect, and as a feature of sanatorium treatment therefore a hydrotherapeutic equipment is essential in the institution.

Occupying the mind of the patient with agreeable, healthful and not too stimulating diversion becomes one of the many problems in the sanatorium. In our climate during the summer, the

wealth of outdoor amusement is such that no difficulty is experienced in the selection of suitable recreation. For ambulant cases croquet, when played as Knopf suggests, with long handled mallets, answers the purpose very well; golf is a most appropriate and healthful amusement, though until the disease is completely arrested the full swing should be strictly forbidden and only the short plays allowed, quoits, outdoor bowling and archery practice have from time to time been popular among the patients of sanatoria and are unobjectionable. Driving, walking and hill-climbing are, however, with us the staple outdoor amusements. In winter the list of possible open air diversions is more restricted. An attempt has been made this winter at the Loomis Sanatorium to introduce some of the Swiss and Canadian amusements, such as skiing, snowshoeing, skating and coasting, so far with only favorable results. In any case, however, winter or summer, a constant vigilance must be maintained to prevent dangerous excesses. The physician must indeed live with his patients—indoors and out-of-doors—and maintain that watchful supervision without which the sanatorium wherever situated whether in the high Alps, the Rocky Mountain plateaus or at the seashore, is an utter failure.

I have purposely not entered upon many very important questions of institutional management and administration, because significant as they are, they do not directly pertain to a discussion of sanatorium treatment. For instance the sanitary arrangements, disposal of sputa and other excreta, disinfection of apartments, bedding and clothing, sterilization of dishes and eating utensils, supervision of the laundry, water supply and innumerable other matters of the utmost importance to the successful management of the sanatorium, but which would divert present discussion from the subject assigned me.

Finally, to sum up in a word, sanatorium treatment of tuberculosis consists in placing the patient in the best possible environment to effect an increase in resistance and to counteract the effects of toxins and waste. To accomplish which we must secure to him, (1) An increased amount of sunlight; (2) enforced rest in the open air day and night; (3) increased consumption of proteids; (4) accurately governed exercise; (5) constant and unremitting medical supervision.

If these desiderata can be successfully secured to him at his home—well and good—so much the better, but from an experience of more than fifteen years in private and institutional practice, with chief interest always centered in the difficult questions of phthisio-therapeutics, I have but rarely seen in the home those fortunate conditions which would allow of anything approaching in value, the benefits of the sanatorium to the consumptive patient, and in conclusion I can but reiterate that whatever in the future may be in store with regard to the therapeutics of tuberculosis, the methods of Brehmer must always hold a place and a vitally important place in the treatment, care and education of the consumptive.

I desire to here acknowledge the valuable aid of my assistant, Dr. William J. Hammer, in looking up and formulating references employed in preparing this paper and in his enthusiastic assistance in carrying out the experiments quoted.

## MEDICAL PROGRESS.

### MEDICINE.

**Blood Cultures in Lobar Pneumonia.**—In a recent investigation the attempt is made to establish more definitely the frequency and time of general pneumococcus invasion of the blood stream and the diagnostic and prognostic value of blood cultures in lobar pneumonia, and also to study the agglutinating and bactericidal actions of pneumococcic blood serum. Eighty-three cases were studied, and positive results obtained in 77. E. C. Rosenow (Medicine, June, 1903) concludes from these experiments that the pneumococcus can be recovered from all cases, if large quantities of blood are used for inoculation, and in obscure cases may be a point of diagnosis of positive value. He agrees with the usually accepted opinion, that pneumococcemia in pneumonia is of no special prognostic value. On account of the difficulties involved, agglutination of the pneumococcus is, at present, of scientific rather than of practical value. Normal and pneumonic blood and serum appear to have no bactericidal influence on the pneumococcus. The interesting question whether lobar pneumonia is the primary result of a direct local infection of the lung, or of a secondary localization in the lung of pneumococci in the blood, is as yet hardly ripe for final discussion.

**Effects of Rest in Bed in Phthisis.**—The favorable effects of rest in bed on the fever of phthisical patients are explained by Pickert (Münch. med. Woch., May 12, 1903) on the ground that the horizontal position assumed, produces circulatory conditions in the lung, which resemble the congestion hyperemia in bone tuberculosis. In the latter instance this phenomenon is known to have a favorable effect. If this theory is correct, the fever ought to return or be increased, whenever the lungs become anemic. Observations have shown that if patients who have been kept in bed until the fever had about disappeared, were permitted to remain up for a certain length of time, the temperature would be immediately increased. The amount seemed to depend to some extent on the fact, whether the feet were allowed to rest on the floor, or kept in a horizontal position. In the former case, the venous hyperemia in the lower extremities undoubtedly produced a diminution in the quantity of blood in the upper parts of the body. Systematic trials showed, in fact, that the difference amounted at times to 1.5° on those days when the patients had assumed the erect posture.

**The Prophylactic Value of Urotropin in Typhoid.**—In a certain number of cases of typhoid, there is a more or less marked excretion of typhoid bacilli in the urine. Urotropin has been employed in a number of

instances, but was found merely to inhibit the growth of the bacilli, and not to cause their disappearance. E. FUCHS (Deut. Arch. f. klin. Med., Vol. 70, No. 1) has lately made some further experiments to determine its prophylactic value. The excretion of the bacilli begins just before or shortly after defervescence, and should continue well into the period of convalescence. The cases observed were divided into two groups, the first included 75 in which no prophylactic measures were attempted. In 10 per cent. typhoid bacilli were found in the urine. In 40 cases 2 grams of urotropin were given daily during the time above indicated, and in only one case, and that a severe one, were any bacteria found in the urine. The author explains the action of urotropin in these cases as follows: In a certain number of instances typhoid bacilli find their way into the circulatory stream and are excreted by the kidney. During their stay in the urinary passages they may multiply and become encysted in certain localities, preferably the pelvis of the kidney and the bladder, and remain quiescent for a long period. Urotropin administered at this time has no effect, as its action is entirely an inhibitory one and does not reach the encysted bacteria. However, if the drug is administered before this can take place, further multiplication is stopped and the remaining germs are excreted. The author is convinced from his experience that the prophylactic use of urotropin in typhoid will absolutely prevent the appearance of the germs in the urine.

**Axillary Adenopathy and Incipient Tuberculosis.**—The importance of axillary adenopathy in the diagnosis of incipient pulmonary tuberculosis was first pointed out by C. Fernet in 1899. According to this author, the condition is present in one-third of the early tuberculous cases; and Allard in 1901, observed 13 cases, within a few months, in which two to three enlarged glands were present either at the apex of the axilla or upon its internal wall. S. CERAULO (Gazz. Osped., May 24, 1903) has made a study of the clinical value of this sign in 11 cases in which there was strong reason for suspecting incipient pulmonary tuberculosis. Bacilli were present in the sputum of two of the cases studied. Enlargement of the axillary glands was found in but one case out of the total number. Ceraulo considers cardiac palpitation and phosphaturia of far greater importance in the diagnosis of incipient tuberculosis; the former having been present in seven cases out of 11, and the latter in nine. These two symptoms, accompanied by fever, cough, etc., he holds to be highly suggestive of incipient pulmonary tuberculosis.

**Arrest of Tuberculosis by a Secondary Infection.**—A contribution to the solution of the question concerning the possibility of the arrest of pulmonary tuberculosis by a secondary infection is made by T. SILVESTRI (Gazz. Osped., May 24, 1903). The author reports two cases of undoubted pulmonary tuberculosis—the diagnosis having been confirmed by bacteriological examination of the sputum—in which a permanent cure followed what he believes to be a secondary streptococcic infection. This was marked by chills, high fever, headache, delirium, lumbar pains, epistaxis, nausea, hemorrhagic macules upon the entire body, hemoglobinuria and blood-streaked feces. These symptoms persisted about fifteen days in both cases; and after their subsidence, a noticeable improvement was observed in the lungs, expectoration, cough and general condition; and at the end of three and four months respectively, a complete cure of the pulmonary lesion was seen in both cases, and the cure has been a permanent one. Examination of the blood was not made, but the author believes the secondary infection to be streptococcic; and bases this belief upon the findings of Haushalter and Etienne, which indicate that the hemorrhagic manifestations in variola, scarlatina and other exanthematous diseases are due to streptococcic infection. He attributes the healing of the pulmonary lesion to a modification of the soil by the secondary infection, which rendered the fertility and vitality of Koch's bacillus impossible.

**Laryngeal Spasm and Pseudomeningitis from Ascaris Lumbricoides.**—Two interesting cases are reported by G. PIERANTONI (Gazz. Osped., May 31, 1903), the first presenting the symptoms of laryngeal stenosis, the second those of meningitis. In the first, papillary mydriasis suggested the presence of ascarides, and upon administration of santonin and calomel followed by rectal injection, there occurred emission of ten ascarides, after which there was a complete subsidence of dyspnea, and no return of the spasmodic laryngeal attacks. The second case presented a perfect clinical picture of meningitis, though no focus of infection could be discovered. It was thought that the trouble might be attributable to auto-intoxication from the gastro-enteritis present, possibly combined with helminthiasis. Again administration of santonin and calomel was followed by emission of numerous ascarides and subsidence of symptoms. The author emphasizes the value of mydriasis as an indication of the presence of ascarides. Of special significance was this symptom in the second case, as it was present in the period of excitation, at which time myosis is seen in true meningitis. Pierantoni believes with Dematteis, who caused the death of rabbits by injection of an extract of *Ascaris lumbricoides* and reported the pathological findings in the animals post mortem, that these parasites secrete a toxic substance and to that are due the anemic and nervous symptoms seen in helminthiasis.

**Variations in the Liver.**—In the healthy subject, percussion reveals a variation in the lower limit of liver dulness amounting to two or three centimeters in one day, according to the conditions of the examination, such as the fasting state, before or after exercise, etc., writes C. MONGOUR (Jour. de Méd. de Bordeaux, May 31, 1903); and in gastro-intestinal affections and other diseases, notably in typhoid, the author has noted variations in the volume of the organ amounting to 4 or 5 cm. within a day. The variations in the liver's size in saturnism, alcoholism and cirrhosis of the liver have been carefully studied by Mongour. In saturnism and alcoholism, he found that during the first ten to fifteen days the liver remained unchanged in size; then succeeded a period of progressive augmentation of volume lasting about three weeks, at the end of which time there began a gradual decrease in volume, though the organ never entirely regained its original size; and from that time on it underwent the daily, normal variations of the healthy liver, this condition being reached after a cure was affected. Out of four cases of so-called atrophic cirrhosis with ascites, the lower limit of the liver remained unchanged in three patients after tapping of the fluid, and these succumbed to the disease; while in the fourth, the liver measured 7.7 cm. after the first tapping, 15 cm. after the second and 17 cm. after the third and last tapping; and from this time on, the liver maintained an average of 14 cm. A cure of three years' duration is reported. In favorable cases, a decrease in the size of hypertrophic livers, followed by daily normal oscillations, after withdrawal of ascitic fluid, was also seen. From these findings the author concludes that such variations in the volume of the liver during the course of a given disease are of great importance in determining the functional value of that organ, and are an indication of the suppleness of the parenchyma and of its power to adapt itself to the

needs of the organism under the variety of conditions which influence its function.

**Poisoning by Lysol.**—Considering the almost universal use of lysol in obstetrical practice, it seems remarkable that more cases of poisoning are not reported. F. HAMMER (Munch. med. Woch., May 26, 1903) believes that such cases are not rare, but as the symptom complex attending them is little understood, their diagnosis is not a simple matter. He reports one case where, on account of the presence of fever during the puerperium, an intra-uterine douche of lysol (1 per cent.) was given. The patient had a placenta previa. Immediate collapse took place, and, although the woman rallied, another collapse with death followed on the tenth day. An autopsy was done and the author explains the case as follows: As a result of the intra-uterine irrigation, a quantity of the lysol solution was aspirated into a vein, some of which reached the brain and caused collapse, but from which the patient rallied. Part of the solution remained in the vein, causing an erosion of the vessel walls and leading to the formation of a thrombus. The latter gradually extended and finally caused death. The author also carried out some animal experiments, by injecting solutions of various strengths under the skin in mice. The results confirmed the observations made at the autopsy of the woman detailed above, and led to the caution that when this drug is used for intrauterine irrigations, it must be used in very weak solution. Any marked degree of pressure must also be avoided, especially in cases of placenta previa, on account of the more gaping condition of the veins.

**Colon Infection Simulating Typhoid.**—It is now possible to distinguish between typhoid and paratyphoid infections, although the clinical course of the two diseases may be very similar. The question arises whether there may not be a type of disease resembling these, but produced by an organism closely simulating their specific bacilli, namely the colon bacillus. The blood serum of animals infected experimentally with different varieties of the colon bacillus will cause it to agglutinate promptly. There seems to be good reason to believe that in certain forms of pyogenic colon infection the specific reaction with the colon bacillus has been obtained, but owing to the great variability in this organism, the results have been very confusing. J. EVANS and J. SAILER (Univ. Penn. Med. Bull., June, 1903) report a case of this kind, of continued fever, in which the blood did not react to either the typhoid or the paracolon bacillus, but where the disease was actually due to a general colon infection. The patient appeared to have an ordinary attack of typhoid, but the blood constantly showed a negative reaction with the typhoid bacillus. The same result took place with the *Bacillus paratyphosus*. Tests were then made with cultures of *Bacillus coli communis* with a positive result, agglutination taking place even in a dilution of 1:100. All sources of error were carefully considered by the authors and they conclude that the case was one of pure colon infection. A direct blood culture was not made.

## SURGERY.

**Auto-epidemic Skin-grafting.**—A very convenient and seemingly efficacious method of skin-grafting is described by H. F. MCCHESNEY (Med. Rec., June 13, 1903). After the area has been gotten into a healthy condition it is cleaned off with Tiersch solution and then irrigated with normal salt-solution. The surface is dried with gauze sponges and where granulations are firm and healthy grafts are applied directly. If exuberant, they are cut down and where flabby they are cut away till a firm fibrous foundation is reached. Then the thin blue line of epithelial cells that have started to creep in along the edge of the wound is dissected up and small pieces about an eighth of an inch square are cut off and placed on the granulating surface already prepared. These are placed with the raw surface against the newly prepared surface and covered with pieces of oiled silk protective about an inch square. These newly developed epithelial cells are very active in their growth and the grafts take very well. At each dressing new islands may be started with very little discomfort to the patient.

**Excision of Tongue.**—One of the most remarkable series of cases of major operations is that reported by W. WHITEHEAD (Practitioner, May, 1903), who described his operation for excision of the tongue in 1891 and cited 130 cases, upon whom he had operated with only three deaths. He has since operated upon 50 more cases without any deaths. These patients include only those in whom the growth was confined to the tongue. In regard to the differences of opinion among surgeons relative to the method of excising the tongue, he says that there are four principal disputed points: (1) Division of the jaw; (2) the use of the écraseur; (3) preliminary tracheotomy, and (4) preliminary ligature of the lingual arteries. Division of the jaw he considers unjustifiable because of its great danger and because of its needlessness, even when the glands are removed. The use of the écraseur is a notable example of deviation from the common principles of surgery and the instrument should never be employed. Since the operation which he recommends guards sufficiently against the air passages being invaded by blood and septic materials he never advises a preliminary tracheotomy and maintains, furthermore, that the mortality from this preliminary operation is even greater than from excision of the tongue. Preliminary ligature of the lingual arteries is also held to be unnecessary for the average surgeon can more easily secure the arteries in the mouth than in the neck. In describing his method of operating he lays much stress upon the position of the patient, which should be such that a change from an upright to a horizontal position may be secured at a moment's notice. He always uses an ordinary rocking chair with high back and the patient's shoulders are fastened to the back of the chair by a towel passing under the arm and over the shoulder, but not across the front of the chest. Any desired position of the body can thus be obtained quickly without any embarrassment of respiration. The tongue is first seized with a pair of forceps and a strong ligature passed through it for traction which is very important. The frenum is then divided by scissors and one blade slipped under the mucous membrane at this point and carried along the floor of the mouth on one side to the pillar of the fauces when the scissors are closed. The same is done on the other side when the whole tongue is to be excised and when the anterior pillars are cut nearly the whole tongue can be pulled out of the mouth, and there need be little fear subsequently of blood getting into the air passages. If the operator is then afraid to cut further with scissors or scalpel he may use a blunt dissector from this point on, by which the tissues may be broken down and torn asunder, exposing the arteries and nerves. The arteries should be clamped, the distal end cut and the stump twisted. If there is no immediate bleeding subsequent hemorrhage need not be feared. Having twisted each artery, he advises that a loop of a strong ligature be run through the stump to prevent its falling back too far when the tongue is finally removed. It is also of service in case of secondary hemorrhage, a very remote contingency. Complete separation may be done by snipping or twisting. After the bleeding from the vessels has been stopped and the floor of the mouth dried as much as

possible, a varnish should be applied to the floor of the mouth. He uses an application made by substituting for the spirit ordinarily used in the preparation of "Friar's balsam" a saturated ethereal solution of iodoform, adding one volume in ten of turpentine. The patient is thus able to take liquid nourishment almost immediately after the operation. The patient should be propped up in bed during the first night and should be encouraged to get up on the second or third day. As a sound principle in surgery, it is always desirable, where malignancy is suspected, to expose as far as practicable the whole area of associated glands and to remove every visible particle of fat and gland just as we proceed to clear out the axilla in mammary cancer. It is a well-known and encouraging fact that in cancer of the tongue death generally takes place before dissemination has extended beyond the limits of the cervical glands—that in fact up to the very end, the extent of the disease is within the range, if not the possibility, of surgical eradication.

**Cancer of Lips.**—An excellent series of articles upon epithelioma of the lips and tongue appears in the Practitioner, May, 1903, and in one of these T. STOKER shows that cancer of the lip has been gradually increasing in frequency during the last decade. He does not believe that heredity is at all an important factor in etiology but lays a great deal of stress upon the use of the clay pipe so common among the poorer classes of Ireland, where this affection is most frequent. This disease is rare among non-smokers. Furthermore the cancer usually appears on the side on which the pipe is held and in one very unusual instance of cancer in the middle of the lip it was found that it was the habit of the patient to hold the pipe in the center of his mouth. It is doubtful if syphilis is of any importance as a predisposing cause. The great bulk of cases are in persons over fifty years of age. It is practically never seen in persons under thirty. The freedom of women from cancer of the lip is notable, but this depends undoubtedly not upon the sex but the habit of smoking, which is so rare among them. The upper classes are also comparatively free from the disease, a fact which is explainable by their greater care of their teeth and mouth, but especially because they use a pipe, if they smoke one at all, not made of clay. The clinical course is tolerably definite, spreading to the lymphatic glands below the jaw and later down the neck. The salivary glands are not affected till late and it is very unusual for the tongue to become cancerous, secondary to the lip. In fact, metastatic growths may be looked upon as unknown, death from exhaustion, septic disease of the lungs or hemorrhage, preceding their possibility. The only two conditions to be confused with epithelioma in diagnosis are sarcoma and syphilis. The former, if seen early, will be found to have commenced in the substance of the cheek. It is a rare condition. If the history and examination does not make a case of syphilis clear, a short course of mercury will be conclusive. The only justifiable treatment is thorough excision as early as possible. Since, however, the only secondary manifestations are found in the glands of the neck till rather late in the disease one should not despair too early, even when the disease has become extensive. Operations have been done for recurrences several times with ultimate success.

**Status of X-ray Treatment of Mammary Carcinoma.**—The general desire among physicians to find some more certain and less hazardous method of treating cancer of the breast than radical extirpation, has undoubtedly led many to speak too enthusiastically of this means of eradication. W. J. MORTON (Med. Rec., May 30, 1903) does not believe that the improvement is so constant or so certain as many have seemed to indicate. In the earlier stages, especially when the growth is not deep, the disease is frequently successfully combated. In recurrent cases or in extensive involvements a cessation of growth or even temporary retrogression may be induced but a complete cure is very seldom seen. He urges, however, the use of the X-ray in the earlier cases, for even if a complete cure is not obtained no time has been lost, for the disease may thus be held in check for some time and the outlying fresh areas are easily cleared up. The case is therefore in better condition for the operation and the chances of complete cure are increased. Even in the hopeless and inoperable cases the treatment is justifiable not only on account of the moral effect, but also because of the undoubted prolongation of life, relief of pain and, at times, of an apparent permanent improvement.

**Hypodermoclysis in General Surgical Infections.**—The beneficent effect of hypodermoclysis in general infection is emphasized by G. TOMASELLI (Gazz. Osped., May 31, 1903) in his description of a case of acute osteomyelitis which had its origin in a severe traumatism and which became the focus from which a general infection spread. The condition of the patient gave little hope after local intervention; profound depression, hyperthermia, small frequent pulse, profuse diarrhea, erythmatous and hemorrhagic eruptions upon the skin, grave changes in the blood and numerous bacteria in that fluid, all pointed to a fatal issue. Incision and drainage of the medullary cavity brought about no improvement in the clinical symptoms; and, hyperthermia persisting, recourse was had to abundant injections of artificial serum. Two hypodermic injections of 500 c.c. each were given in one day and a third, of the same quantity, was administered the following day; after which there were slight remissions of temperature and a lessened depression was apparent. A fourth injection, upon the following day, was followed by marked improvement ;and a gradual disappearance of the symptoms of general infection ensued. Cultures from the blood, taken ten days after the last injection, no longer showed development of bacterial colonies and the patient made a complete recovery, which, the author believes, is largely due to the favorable influence upon the general condition of hypodermoclysis.

**Therapeutics of Artificial Venous Hyperemia.**—The attempt to influence local tuberculous processes by producing an artificial hyperemia was first suggested by Bier in 1892. Some further trials of this method are reported by HABS (Münch. med. Woch., June 2, 1903), who used it in over 300 cases, about 200 of which were tuberculous. Chronic inflammations of the joints of the knee, hand and foot were markedly benefited and in many cases the swelling entirely disappeared. This was especially noticeable in children, and the pain and spasm often subsided after a few applications. In other cases the condition grew worse and operation became necessary. The methods employed in the various diseases were as follows: In tuberculosis the constricting elastic bandage was applied during the first week twice daily and allowed to remain in place four to five hours. After this it was applied less day by day, until it was in use only one hour daily. Active hyperemia (hot air, etc.) was not used, but injections of iodoform were given in the presence of joint effusions or unopened abscesses. Large abscesses were incised and fistulæ curetted. In advanced cases, resections are of course indicated. In gonorrheal rheumatism, the elastic bandage should be left in place at least eight to twelve hours daily. After the fever and the pain have subsided, in addition, active hyperemia is employed for the absorption of effusions—a daily session of an hour in the hot sand or electric light bath. In cases of chronic joint adhesions follow-

ing trauma or inflammation, the bandage is applied twice daily for an hour, in addition to massage and exercises, and a hot air bath every third day. For joint inflammations due to chronic rheumatism, he prefers active hyperemia, by the hot air or the electric light bath. For incomplete callous formation, aside from massage and exercise, the passive hyperemia may be used for two hours daily. Freezing, frost-bites and the like are benefited greatly by the application of the elastic bandage twice daily for one to two hours. The method can be recommended for simplicity, painlessness and general utility.

**Talma's Operation for an Adherent Pericardium.**—A case of this type, which was finally succeeded by a general ascites, and in which ordinary methods of treatment were of no avail, is reported by P. CLEMENS (Münch med. Woch., June 2, 1903). As numerous instances are on record where benefit followed this operation in ascites due to hepatic cirrhosis, the patient as a last resort was subjected to the same procedure. The operation was done by Kraske under the Schleich method of infiltration anesthesia, and the omentum sutured to the abdominal wall in the usual manner. An improvement was noted for a time, but permanent relief was not secured. The author believes that failure in his case was probably due to the late date at which the operation was undertaken and also to the advanced cardiac lesion.

**The Abdominal Belt.**—A plea for the abandonment of the abdominal belt after celiotomy is made by M. KAHN (Phil. Med. Jour., June 6, 1903). He claims that the prevention of postoperative hernias depends to a large extent on the perfect approximation and suturing of the edges of the wound. The strength which it is necessary for the muscles to acquire cannot be gained by any supporting or restraining belt, but must be secured by proper exercise. The wearing of a belt relieves the muscles of their usual labor, and there supervenes the atrophy on non-use, whereas it would be desirable to have the hypertrophy of overuse. When the belt is discarded, the attenuated muscles are suddenly called upon to accomplish what is relatively an excess of labor. The author removes all dressings three or four days after the patient is up, sixteen to eighteen days after operation. He has had good results in all cases.

**The Administration of Ether by the Drop Method.**—A further report on this procedure, first suggested by Witzel, is made by F. BERNDT (Münch. med. Woch., May 19, 1903), who employed it with success in 120 cases. The injection of a small dose of morphine was recommended previous to beginning narcosis, but this the author has discarded as unnecessary. The ether is given in such small amounts that after-effects are not seen. In all cases the urine was examined for several days without finding a trace of albumin. The recovery in every instance was rapid. The method is briefly as follows: The patient is directed to count backward from 200, so as to stimulate deep respirations. The ether is then dropped very slowly on a Schimmelbusch or Esmarch mask, and after a certain degree of narcosis is attained, taking from ten to twenty minutes, a few drops of chloroform are given until the corneal reflex is abolished. The ether is then resumed and the chloroform may also be again given, a few drops at a time, whenever the patient appears to become restless. The patient's head should be kept low and bent sharply backward. When the chloroform is added, it is claimed that the heart is already stimulated and strengthened by the ether and so better able to resist the effects of this drug.

**Cocaine Herniotomy.**—In order to lessen the mortality for this operation in every way possible, and minimize the fear of serious results which seems so general among the lay people, it has been suggested and during the last year or more many surgeons have proven that the operation may be successfully performed under a local anesthetic. A. LYLE (N. Y. Med. Jour., May 30, 1903) has performed 15 such operations, and now uses the local anesthetic by preference, even when there is no contraindication to ether or chloroform. After cutting down upon the aponeurosis of the external oblique, the fibers of which may be easily separated, the iliohypogastric and ilio-inguinal nerves can usually be easily found and two or three minims of a quarter of one-per-cent. solution of cocaine should be injected into the trunks. If the genital branch of the genito-crural nerve can be found that, too, should be cocainized. The operation may then be proceeded with without pain to the patient and a thoroughly radical operation performed. Care should be taken not to cut any good sized blood vessels, for there is always pain on ligating such a vessel unless the parts are thoroughly anesthetized. The cocaine solution should be fresh, hot, and sterile. The advantages claimed for this method are: (1) we have eliminated all danger of a general anesthetic to the heart, lungs and kidneys; (2) we have cut no nerves, consequently the nerve functions remain unimpaired; (3) not a single vessel has been ligated, for none of sufficient size for ligation has been divided, and (4) there is no shock, no nausea and no straining.

**Sodium Bicarbonate in Surgery.**—Solutions of sodium bicarbonate have been much lauded for the bathing and dressing of wounds, and in the treatment of atonic ulcers, especially the varicose. C. LEVASSORT (Jour. de Méd. de Paris, May 10, 1903) has had recourse to the drug in powdered form, dusting it abundantly into the wounds, ulcers, etc., and then tamponing with sterilized gauze. He allows the gauze to remain in cavities so treated from fifteen to twenty days; simply withdrawing and cutting off a portion of the dressing every two or three days as the cavity fills in with granulations from the bottom and sides. When the remains of the first dressing are removed, the author states, the work of repair is found to be well advanced; healthy granulations having formed and reduced materially the depth of the wound. A second dusting with sodium bicarbonate and dressing with sterilized gauze is said to complete the cure. Levassort has used this method of treatment for the past five years; and, in his experience, healing proceeds more rapidly with this method than with any other. The application of the soda is followed by some discomfort—burning and itching—but this is said to subside within fifteen to twenty minutes.

## OBSTETRICS AND GYNECOLOGY.

**Obstetrical Paralysis.**—In the infant the earlier writers appear to have assumed that this injury was due to direct pressure on the nerves, says WILLIAM THORBURN (Brit. Jour. of Obstet., May, 1903). Pressure on the neck, however, is incompetent to injure the lower roots of the plexus, while pressure in the axilla would not select for injury the fifth and sixth roots only. The appearance of Erb-Duchenne paralysis at the time of birth is not very common; statistics quoted by Duval and Gullain showing that it may be expected about once in 2,000 births, and that in the vast majority of cases delivery has required some operative interference, while nearly one-half have been breech presentations. Lateral stretching will obviously bear most heavily upon the upper cords of the plexus, and will thus explain the selection for injury of its fifth and sixth

roots. This brings the causation of obstetrical paralysis of the Erb-Duchenne type into line with that of ruptures of the entire plexus and allows the assignation of all cases to direct traction, the only difference being that in the former the plexus is stretched by deflection of the head, whereas in the latter the impact is more commonly received upon the shoulder. The prognosis of injuries of the brachial plexus, whether obstetrical or otherwise, is unsatisfactory and Bruns has recently shown that of all cases of partial injury, only 26 per cent. recover, whereas 66 per cent. of similar injuries to single nerves below the plexus undergo spontaneous cure. The treatment of obstetrical paralysis has, until recently, consisted solely in the use of warmth, massage, galvanism, and the like. In cases of the Erb-Duchenne type arthrodesis at the elbow may be of service, but though this measure was suggested in 1886 it is not known that it has been actually carried out by anyone. Of primary suture of the plexus and its root there are numerous cases. Kennedy has now extended the operation to obstetrical paralysis, and reports three cases in all of which the cicatrix was situated at the junction of the fifth and sixth cervical nerves. The first operation was performed two months after birth, the second fourteen years after, and the third six months after, and suggests two months as a reasonable period to wait for spontaneous recovery. The result was excellent, but the operations had been of too recent a date to judge what the final outcome of the cases might be. On the evidence before us it may be safely assumed: (1) That in the vast majority of cases of obstetrical paralysis the cicatrix will be found in accessible places at the junction of the fifth and sixth roots; (2) that recovery without operation is highly doubtful, and is certainly not to be expected unless marked improvement occurs within the first two or three months; (3) that if marked improvement does not occur within this period the plexuses should be exposed; (4) that perineural cicatrices should be removed and the nerves resected unless they are free from internal callus; and (5) the results of such operations are likely to be favorable.

**Double Pregnancy in a Double Uterus.**—A case of this variety in a woman, thirty-four years old, who had had three previous normal labors, is reported by J. B. HELLIER (Brit. Jour. of Obstet., May, 1903). She ceased to menstruate in the middle of May, 1902. During pregnancy the uterus was unusually large and there was a great deal of abdominal pain and edema of the feet. Labor began January 28, in the forenoon, and a living child was born at 5.30 P.M., the head presenting. The placenta followed. On abdominal palpation the presence of a second child was recognized, but the uterus showed but little tendency to expel it. At 11 P.M. the hand was introduced into the uterus and it was found to be empty. One hour later, on the second examination, a second os uteri was discovered above and in front of and somewhat to the left of the other, the uterus being rotated on its long axis, a fetal head was just within touch. The second child was delivered by podalic version, and the patient made an excellent recovery. A month later it was found that the uterus was bicornuate and that there was a complete septum reaching down to the cervix. After three pregnancies in one side or the other of the uterus, the two sides became pregnant simultaneously. When labor came on the head in the right descended and dilated the cervix, and in so doing prevented the descent of the other head. The fact that the left cervical canal lay anterior to the right is a phenomenon which has been noticed before. The change which involution produced in the cervix was also striking. The double canal and thick septum were so much in evidence after careful examination at the time of delivery, and yet a month later the septum was so much reduced within the os that the double nature of the uterus and the cervical canal might easily have been overlooked on simple, digital, vaginal examination.

**The Effects of Vaporization.**—A specimen, removed fourteen days after curettage and vaporization had been performed for irregular and frequent menstruation by G. F. BLACKER (Brit. Jour. of Obstet., May, 1903), illustrates very well the effects of superheated steam upon the mucous membrane and muscular tissue of the uterus. From the naked-eye appearance and the examination of the microscopic findings it was evident that not only the whole of the mucous membrane of the body of the uterus and the cervical canal had been destroyed by the action of the steam, but that a considerable part of the mucular tissue had also been destroyed in that part of the cavity of the uterus occupied by the intra-uterine canula. In order to avoid any risk of perforating the fundus of the uterus the end of the canula is not introduced up to the fundus of the uterus, and the large cavity present in the specimen extending of the point 1.8 cm. from the upper limit of the body of the uterus, no doubt represents the part of the uterus exposed to the cauterizing effects of the intra-uterine metal tube, and the extensive destruction of tissue is due not only to the action of the steam, but also to the heat of the tube. The specimen illustrates that by the use of superheated steam it is possible to produce complete necrosis of the uterine mucous membrane, and that where the action of the steam is continued for so long a period as ninety seconds, the destructive action of the heated metal tube must also be taken into consideration. By the use of this method, therefore, complete destruction of the uterine mucous membrane can be obtained almost with certainty. From the entire absence of the glandular or lining epithelium in the specimen, it is evident that no regeneration of a perfect mucous membrane could have taken place. The further examination of the specimen entirely fails to show any evidence of the presence of a carcinomatous growth. It is, however, possible that the destroyed tissues may have been the seat of early carcinomatous degeneration. In cases where the entire mucous membrane has been destroyed, its place is usually taken by a layer of connective tissue containing no glands and covered by a single layer of cubical epithelium.

**On Uterine Action.**—In an able and valuable work by a leading obstetrician of to-day, it is stated that "the principle not to deliver in the absence of uterine contractions is the first point in the prevention of post-partum hemorrhage. Do not pull away the placenta without waiting for uterine contraction." In traction with forceps, he says, "pull with the pains, leaving off pulling between the pains." To this principle so laid down, WM. STEPHENSON (Brit. Jour. of Obstet., May, 1903) takes exception for the following reasons: (1) There are no clinical data in its support; (2) it is not in accordance with the author's experience and that of others who, when necessity has arisen, have not hesitated to deliberately empty the uterus without waiting for pains, and without thereby inducing hemorrhage; and (3) the opinion is a logical deduction drawn from an erroneous idea of uterine action. First let us consider the behavior of the uterus during the operation of Cæsarian section. The operator does not wait for a pain, but as soon as the membranes are ruptured he must deftly remove the child, otherwise he would find himself hampered by the rapid closing of the walls, not from contraction, but retraction; the wall at once resiles when freed from the cause of expansion. Again, he does not wait for contraction before extracting the placenta, but peels it off trusting to retraction to restrain the

bleeding. Secondly, for various complications of pregnancy it has at times been deemed advisable to empty the uterus artificially without at first inducing labor. The cervix is dilated and the child removed without waiting for or even desiring uterine contractions. Does the uterine cavity remain undiminished though empty, and does hemorrhage occur more frequently than under other circumstances? Thirdly, take a case of excessive hydramnios, where the patient is suffering much pain, and from difficulty of breathing she cannot lie down. To afford relief one does not wait for labor to set in but ruptures the membranes without hesitation, and the uterus will steadily retract. Fourthly, in severe hemorrhage in the third stage with retained placenta, or post partum where the uterus has melted away from the grasp, and the fundus cannot be defined by the left hand externally, the author has invariably introduced the right hand to remove the retained placenta. Here one can observe the difference between the sudden closing in the cavity by contraction and the more gradual, often slow, but progressive, action of retraction. The latter is by far the most frequent result. With such evidence as the above study of the subject, can there be any doubt that, apart from contraction, the uterus possesses the power of reducing its volume and capacity when emptied of a part or the whole of its contents. Although Duncan said at the time that he wrote, "that retraction is not dependent is difficult to prove," now that we possess clearer views on this subject his other statement must be accepted as true that, "retraction is a separate and distinct function, that is, it may go on without contraction."

## NEUROLOGY AND PSYCHIATRY.

**Position of the Head in Cerebellar Disease.**—In a current number of Brain DR. FREDERICK E. BATTEN discusses the diagnostic value of the above by attempting to answer three very important questions: (1) Is a definite attitude assumed in cerebellar disease? This is often met with, but is not necessarily present throughout the course of the disease. It is manifest in an approximation of the ear, on that side of the body opposite to the lesion in the cerebellum, to its adjacent shoulder, and in the direction of the face toward the affected side. (2) Is this attitude the same as that following upon an experimental lesion and is the symptom itself of diagnostic value? Only in certain particulars, the following conditions being contrary to those obtained on experimental lesion: Approximation of ear to shoulder on opposite side; reflexes absent on same side; no anesthesia nor analgesia; nystagmus to opposite side. The symptom is less important perhaps than incoordination or weakness viewed from a diagnostic standpoint. It should not be the basis of a positive diagnosis but is to be considered merely as auxiliary evidence. (3) Is this position assumed in intracranial tumor in the absence of gross lesion of the cerebellum? Yes, the symptom occurred in a case cited and was probably due to blocking of foramina around the fourth ventricle. Too much importance should not be attached to the position of the head alone, but more indicative symptoms, such as those already mentioned, must be carefully sought for.

**Regeneration of Posterior Spinal Roots.**—An experimental study for the purpose of determining whether posterior roots are capable of regeneration in their intramedullary portion, has been made by W. G. SPILLER and C. H. FRAZIER (Univ. Penn. Med. Bull., June, 1903). The advisability of the operation recommended by them for the relief of tic douloureux—the resection of the sensory root of the trigeminus—depends largely on the absence of regeneration of these posterior root fibers within the spinal cord, because if the posterior roots are incapable of regeneration, we may assume that the sensory root of the Gasserian ganglion likewise is incapable of regeneration. The experiments were carried out on dogs. A laminectomy of two or three vertebræ was sufficient to expose several pairs of roots. The posterior roots were transfixed at two points with needle and fine silk, a short distance apart, and divided between these points. By tying the suture the divided ends were brought into perfect apposition, and then the external wound was closed. Only one of the animals lived sufficiently long (10 months) for the purpose of drawing any conclusion. Examination showed that the intramedullary portions of the roots operated upon were entirely degenerated, and no young nerve fibers could be seen anywhere in the usual distribution of the posterior roots within the cord. Degeneration could not be seen by the Marchi method, because all signs of recent degeneration, as shown by this method, had disappeared on account of the long time the animal was allowed to live after the operation. Although the conditions were most favorable in this case, no regeneration whatever took place.

**Neuroses from Prolapse of the Kidney.**—The more common of the nervous symptoms accompanying kidney prolapse are, according to A. H. GOELET (Ann. of Gyn. and Ped., June, 1903), vertigo, syncope, palpitation of the heart, restlessness, insomnia, frequent micturition, hysteria and neurasthenia. How often these may be due directly to irritation of the solar plexus it is impossible to say. They are dependent somewhat on gastro-intestinal disturbances, which may themselves be due to irritation of the symphathetic or to direct traction by the kidney on the duodenum. With the kidney prolapse there is constantly associated pain in the kidney region, in the ovarian region, in back, thighs and even the head. Irritability of the bladder, most manifest during the day, may be purely neurotic. The constant suffering, or dragging sensation, or fatigue on slight exertion, together with the digestive disturbances, may lead to hysteria or to neurasthenia. Such patients are never relieved until the kidney is completely detached from the colon, and permanently fixed in its normal position. Albaran believes that the movable kidney is a cause of constant internal trauma, and thus acts on the nervous system. The author thinks operation better than mechanical appliances, because (1) temporary relief of the symptoms does not mean cure; (2) the pressure of a belt or corset provokes undesirable irritation and may induce nephritis; (3) the operation has no mortality, and the cure is permanent.

**Influence of Alcoholic Liquors on Digestion.**—At present there is apparently no consensus of opinion regarding the influence of alcoholic liquors on digestion, probably on account of the different results obtained by various methods of experimentation, and also from the disposition to rely on clinical experience rather than on laboratory results. R. F. CHASE (Phil. Med. Jour., June 6, 1903) has lately made some experiments to determine what influence whisky and beer, taken with meals, had on gastric digestion. These articles, and also tea or coffee, were given with an Ewald's test meal on an empty stomach on alternate mornings. Analysis showed that salivary digestion was slightly delayed by whisky, and somewhat accelerated by beer. Peptic digestion, both in the stomach and in the test tube, was noticeably delayed by whisky and in a more marked degree by beer, in the latter case quite out of proportion to the amount of alcohol contained in the beer. Thus it would seem that liquor taken with meals, exercises on the whole only a harmful influence, while in cases of gastric disease its use is not followed by any beneficial results. The tests made with tea and coffee showed

that in the amounts ordinarily used, they do not retard either salivary or peptic digestion, but that salivary digestion is accelerated slightly by tea. The results also show that these fluids also act as mild stimulants to gastric secretion, the digestive power of the secretions is not augmented, but on the other hand is not impaired, as in the case of whisky. Admitting the generally harmful effects of large quantities of tea and coffee, the author believes that an undue prejudice has been excited against the use of these beverages by the results obtained from laboratory experiments.

## PATHOLOGY.

**The Influence of Formaldehyde on the Blood.**—The recent use of formalin in septicemia lends a peculiar interest to the research conducted by C. C. GUTHRIE (Am. Jour. of Physiol., June 1, 1903), on the effect of this gas on the coagulation and other phenomena of the blood. He found that coagulation is retarded in blood drawn into solutions of this gas in proportion to the amount of formaldehyde present. In sufficient amount, the latter prevents coagulation indefinitely. The average amount of formaldehyde necessary for this purpose in various animals, is 1 to 185.5 parts of the blood. Amounts of formaldehyde too small to prevent coagulation, prevent the clot from advancing beyond a delicate, jelly-like stage, for a period proportionate to the amount of formaldehyde present. The onset of spontaneous laking (solution of hemoglobin in the plasma) at room temperature, is not markedly delayed by small quantities of formaldehyde, but, once begun, it proceeds much more slowly than in normal blood.

**Infectivity of Scarlet Fever.**—During recent years there has been considerable change in the attitude of medical officers of health in regard to the communicability of scarlet fever. There is considerable doubt expressed now about the highly infectious nature of the disease during the later desquamating stages. L. C. PARKES (Practitioner, April, 1903) notes the change of view which has occurred in England and attributes it to the following reasons: (1) Desquamation is not a manifestation of scarlet fever alone and although more complete in this disease, yet the more moderate peeling of measles and Rötheln has not been considered as being of specially infective character; (2) the similarity between scarlet fever and diphtheria seems to point to an infective organism for the former similar in character to that of the latter. In each disease the tonsils and soft palate are the parts usually affected first. The tonsillar and buccal mucus is the home of the diphtherial contagion and it would seem probable that the same secretion is ordinarily the habitat of the scarlet fever virus; (3) fever hospitals which have taken to discharging patients before desquamation has ceased have not shown any increase in the "return" cases. Since the bacteriology of scarlatina has not yet been settled it is, of course, impossible to be positive about the most dangerous stages of the disease and hence it would perhaps be unwise to relax any of the present rules in regard to quarantine. In spite of the increasing numbers of carefully isolated cases each year there seems to be no appreciable difference in the prevalence of the disease, and as the expense incurred by this long confinement is such an important item, the necessity of it may well be questioned. The mortality of the disease, however, is constantly decreasing and is now only one-eighth what it was forty years ago. That again is another reason why less rigid rules may soon be expedient.

**Fruit Vessels, Mosquitoes and Yellow Fever.**—A practical investigation of this subject has been made by E. SOUCHON (Jour. Am. Med. Assoc., June 13, 1903), for the purpose of explaining certain facts in connection with the *Stegomyia* as a carrier of infection. The scarcity of *Stegomyia fasciata* on fruit vessels from ports quarantined against yellow fever was shown by the fact that out of 208 mosquitoes captured on a number of vessels plying between New Orleans and Central America, only 2.5 per cent. were of that species. In houses, however, the number was 40 per cent. The females were largely in the majority. The vessels plying between New Orleans and Havana furnished 16 per cent. of *Stegomyia*. During the fifteen years from 1886 on, only five cases of yellow fever were brought by these vessels to New Orleans, and in only one instance could the infection be traced to the ship, all the others, contrary to regulations during the quarantine season, had communication with the shore. The impunity of intercourse with non-infected vessels is shown by the fact that laborers constantly entered the holds of these vessels while in port and before fumigation had taken place and yet from 1886 to 1895 not one case of yellow fever originated in New Orleans. It was also found that the *Stegomyia* on non-infected vessels are not infected, as evidenced by the free intercourse just noted, although yellow fever was epidemic in the ports of call during the period in question. It is improbable that *Stegomyia* on infected vessels become infected before reaching the quarantine station because the percentage is so small (2.5 per cent.), the females must become impregnated before they will bite, the males on board are a few in number, the females must bite the patient within the first three days and cannot infect a human being until twelve days thereafter, the mosquitoes do not breed in sea or bilge water, the bitten subject must be non-immune and the cases on record are all primary. In the case of New Orleans at least, it is impossible for any mosquito to carry yellow fever into the city, because fruit vessels are not more than six days in transit before reaching the quarantine station, where all the insects are destroyed by fumes before the twelve days have expired. The author also found that mosquitoes will not live without moisture or water for more than three to five days during the summer months, which proves that there is very little liability of their being transported in baggage.

**Duration of Life of the Yellow Fever Mosquito.**—The laboratory experiments conducted by JUAN GUITERAS (Rev. de Med. Trop., April, 1903), to determine the duration of life in the *Stegomyia fasciata* are of special interest in view of the fact that that insect retains its infectivity throughout its life. He thus describes his work: Eighteen mosquitoes, which were hatched on August 1, 1902, were made to bite, on the fifth of that month, a patient suffering from a fatal form of yellow fever; and of this number, seven were killed for the purpose of studying their salivary glands and intestines. The remaining eleven died after a period of from five to one hundred and fifty-four days.

## THERAPEUTICS.

**The Action of Camphor on the Heart and Blood-vessels.**—The use of camphor in conditions of collapse and heart-weakness, according to H. WINTERBERG (Pflüger's Archiv, Vol. 94, Nos. 9 and 10), was founded originally on an empirical basis. The experimental investigation of the action of this drug on the mammalian circulatory system would seem to dethrone camphor from its place among the valued cardiac stimulants. The author found that the chief action of camphor upon the blood-vessels consists in a dilatation of the same, particularly in the areas of the vessels drained by the jugular and femoral veins. The point of attack in the production of this dilatation is to be sought in the periphery. The direct exhibition of camphor in the blood-current produces a slight and transient stimulation of the vaso-

motor centers, expressing itself occasionally in a slight rise in blood-pressure, followed by a rapid fall. Sometimes there are noticed, after the administration of camphor, certain undulatory variations in the blood-pressure, occurring at irregular intervals. These are to be attributed probably to a reflex excitation of the vasomotor centers, following the increased irritability of the latter produced by camphor. There is no evidence of any favorable action of the drug upon the work of the heart, although there is no evidence of any damage to the heart from small and moderate doses. The cause of the diminished blood-pressure is to be found in the dilatation of the smaller arteries. The consequent acceleration of the flow of blood and the synchronous diminution of frictional resistance, tend to explain the absence of change and even the slight increase of pressure in the left ventricle. The above results show no favorable action on the heart and reveal but an inconstant excitation of the vasomotor centers. The somewhat regular periodic rises of blood-pressure appear only after doses too large for therapeutic uses. The author's researches contradict the results of clinical experience, yet he would not withhold from camphor any medicinal value for, irrespective of its power of stimulating the cerebrum and the respiratory center, manifesting itself in an acceleration and deepening of respiration, the vasodilating property of this drug, by regulating the distribution and circulation of blood, is all the more significant, inasmuch as all the vascular territories do not share equally in this dilatation. Particularly the vessels of the splanchnic area are not dilated by camphor. Whether its capacity to lower the bodily temperature, and whether the common experience that after the subcutaneous administration of camphor, a hardly perceptible pulse is again made easily palpable, are to be attributed to this arterial dilatation, can only be determined by clinical investigations along this line.

**Two New Peroxides.**—This interesting class of chemical compounds has of late years received a large amount of attention. In a recent communication N. FRAENKEL (Progres Médicale, 1903, No. 2) has contributed a study on two metallic peroxides made from zinc and magnesium. These have been termed dermogen and diogen. The indications for use of these two new compounds are similar to those of other peroxides with certain modifications because of the presence of the metallic ion. Dermogen is a faintly yellowish powder, light, tasteless, odorless and insoluble in water. It is used externally almost exclusively and sets free nascent oxygen in about 9 per cent. Biogen is a light, tasteless, odorless and insoluble powder and is used internally. 1 gm. 15 grs. of the magnesium peroxide in the stomach is capable of producing one-half gram of hydrogen dioxide. Biogen is decomposed by the gastric juices, and the hydrogen dioxide formed is broken up and free oxygen results. This acts as an antiseptic and oxidizer and is thought to penetrate the tissues passing in through to the stomach wall. Its therapeutic indications have not as yet been thoroughly studied, but it offers an interesting field for clinical observations.

**A New Form of Focus Tube.**—In a paper on the subject of a new form of focus tube, C. W. ALLEN (Jour. of Cut. Dis., April, 1903) says that the rays from the target in the focus tube now in use do not emanate in all directions with equal intensity, but follow the same rule as light waves from a flat illuminated surface, and are the strongest in a line at right angles to the surface, and steadily decrease at every increase of the angle of obliquity. In the case of illuminating rays, as is well known, the decrease is as the cosine of the angle, and in a direction corresponding with that of the plane of the illuminated surface, the light becomes nil. In the case of the X-rays it may be assumed that the rule would be the same if the rays came from a geometric point, but on account of the size of the area from which the rays emanate, there are some rays at the plane of the anode. The greatest intensity of the rays is, as in the case of light rays, in a direction perpendicular to the plane of the anode, and in a line passing through a point in the anode at which the cathode stream impinges. It is therefore very inconvenient in the tube of ordinary construction to utilize these rays on account of their direction being away from the center of the tube and in a direction toward the cathode. In the tube presented by the author, devised by Dr. Milton Franklin, the rays of greatest intensity pass from a tube in the direction corresponding with the center of the free side of the bulb, and the strength of the rays at any angle to the right or left of this center will be the same. In aiming the rays at any part, an exact indication of the direction of the most powerful rays may be obtained from the annex through which the target support is directed. The essential feature of the tube, and wherein it differs from the others is in the position of the target and the cathode. The annex through which the target enters is placed midway between the other two provided for the second anode and cathode, and the plate of the target placed at right angles to its stem, presents a plane at right angles to a line passing through the free boundary of the tube midway between the anode and cathode annexes. The cathode is inclined to its stem in an angle of about 30 degrees so that the cathode stream impinges upon the target at an angle of about 60 degrees.

**Prophylactic Against Poisoning with Rhus.**—A thorough investigation of the nature of the poison of rhus discloses the fact that it resides in a poisonous oil which is communicated by osmoris from the lactiferous ducts of the leaves and stems to small hairs which grow upon the vessels and which are easily broken off and carried by wind or direct contact to the skin. C. SCHWALBE (Med. Rec., May 30, 1903) says that the ordinary neutral soaps will not neutralize the toxicondric acid, especially as these little hairs are liable to lodge and remain in the openings of the sudoriferous glands. If the exposed skin is bathed frequently with a one-half-per-cent. solution of potassium carbonate the poison will be destroyed. A 1 to 1½-per-cent. solution of ammonium chloride is also highly recommended as a prophylactic and also as a curative remedy.

**Calcium Chloride in Hemorrhage.**—In numerous instances, this drug has yielded, in the hands of J. C. REEVE (Am. Gyn., April, 1903) most excellent results in the control of bleeding. As it is well known, it is relied upon by Mayo Robson and others as a valuable means of forestalling chronic hemorrhage in gall-bladder surgery. Yet the latest works on therapeutics make no mention of it, and it has received but scant mention by the profession at large. Certain writers have even disputed its efficacy. The writer reports a case of a woman who entered his wards with profuse hemorrhage. Circumstances prevented operation at the moment and calcium chloride was prescribed. Several hours later the resident physician summoned the writer in haste under the belief that she had sustained an inversion of the uterus. A firm, pear-shaped body was found to be protruding several inches from the vulva with blood still trickling over its surface. On examination the tumor was found to consist solely of concentric layers of coagulated blood, which had grown as a stalactite grows, by successive depositions. Since the coagulum had formed only after the exhibition of the calcium salt the experience may be taken as going to prove the efficacy of the chloride of calcium in raising the coagulability of the blood.

# THE MEDICAL NEWS.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## WEIGHT AND MENSTRUATION.

MANY and varied theories have been evolved from the inner consciousness of supposedly observant gynecologists with regard to the nutritional changes incident to menstruation. A rather prominent physiologist and author of a text-book on physiology in England predicated a distinct connection between the moon and menstruation, since, according to a large number of statistics most women menstruated during the first quarter of the lunar month. What is needed in this matter is more careful observation to determine what are the nutritional factors and the effects on metabolism of menstruation in the human female. Dr. Belfield, of Chicago, in a recent number of the *Journal of the American Medical Association* (June 13, 1903), seems to have opened a new field of investigation in this matter. He has found that there is a distinct weight wave of menstruation, that is to say, shortly before menstruation there is a distinct gain in weight, followed by a still more rapid loss of weight immediately after the flow has ceased. This loss in weight is not at all proportionate to the amount of material lost as menstrual blood, which is, after all, only a trifle, seldom amounting to more than a few ounces in the normal woman.

Dr. Belfield has found that in winter especially from 2½ to 5 pounds, which may be from 1½ per cent. to 5 per cent. of the subject's usual weight, are gained during the four or five days immediately preceding the beginning of the menstrual flow. The climax of this gain is immediately followed by the rapid loss of a large part, perhaps half, of this increase in weight (often within eight to sixteen hours) and then a more gradual loss of the remainder, extending over several days. He has found further that the premenstrual gain in weight is due not to increased ingestion of food, but to the diminished excretion, especially of water. On the other hand, the rapid loss of weight following the crest of the wave, is due not to abstinence from food but to rapid excretion, especially of carbonic dioxide and water. In one case Dr. Belfield observed a loss of 2½ pounds in weight during the five hours following the appearance of the menstrual flow, though neither urine nor feces had been voided during that period, and though the subject had had no exercise other than that incidental to clerical office-work indoors.

These observations of Dr. Belfield's are confirmed by the fact often noticed by women that apparently their flesh feels firmer just before a menstrual period begins and that this may be the preliminary warning that the flow is about to commence when they have forgotten the exact date at which menstruation should occur.

Nearly every gynecologist must be familiar with this story, though it has usually been put aside as of no special significance, or as being one of these vain imaginings that women are so apt to have about this time. As might be expected under the circumstances, the temperature curve during these rather marked changes in metabolism is not constant. There is usually a rise of about 1° F. during the days in which the increase of weight is most noticeable and a sudden fall after the crest of the weight wave is passed. It is probable that there is a more than corresponding variation in the pulse since the rapidity of the heart action is even more dependent on general metabolism than is the temperature range.

These observations are of the direct objective character that mean a distinct gain in knowledge. Much remains to be done to supplement them in order to understand the metabolic principle on which they occur. It is not improbable that the mystery of the influence of the ovary on nutrition and of the question of an internal secretion from this organ, as seems almost surely to be the case, from many recent observations, may be solved by

the continuance of this investigation. The data are rather easy to obtain and there is opportunity for physicians in different parts of the country to tell us how much temperature and climatic changes of various kinds may influence metabolism in association with these menstrual alterations of weight and general condition. In a word, an attractive subject for investigation is here presented, upon which it is to be hoped many observers will find opportunities for research.

## "BERRIES AND CREAM."

The bray of the ass once more breaks the stillness of the air. An editorial in the New York *Times* of June 10, with the above heading, sarcastically points to the work of the German Consular office in estimating the number of bacteria contained upon the various fruit products that are consumed at this season of the year, with contemptuous ignorance and derision. Aspersion is cast at the counting of germs in milk and cream, and it is inquired, "What can be the popular value of this sort of information?"

Our esteemed contemporary has evidently lost track of the well-known happy results that have come from just such research work. What brought about the establishment of the now recognized indispensable Straus milk stations? It was nothing more or less than the painstaking investigation of the germ infection of the fresh milk and cream "just from the cow" that determined these to be the cause of the yearly death-dealing, devastating plague that each summer had carried off the children of the rich and the poor alike.

What induced John D. Rockefeller to donate millions of dollars toward the establishment of an institution for medical research of this kind?

It has been this selfsame sneering ignorance that has for centuries prevented the onward progress of science in all its branches, and it is painful to see it in the columns of one of the ablest of our New York dailies.

It is a well-known fact, even to the laity, that the spread of disease by means of infected fruits may readily take place. Epidemics of cholera and yellow fever have had their origin in the introduction of certain fruit products both in this and other countries. In Japan it is impossible to eat raw vegetables because of the liability of infection with the ova of certain animal parasites of many varieties, chief of which is the most annoying tapeworm. The Italian fruit vender, the purveyor of the city's fruit supply, polishes his wares by expectorating upon them and then gives to them a beautiful luster by means of a dirty rag pregnant with syphilis or what not. The farmer deposits his feces in the brook running through his ten-acre lot and the eggs of the harmless tapeworm and other parasites find a resting place upon the leaves of the favorite watercress, soon to make its way to our tables and thence to our alimentary tracts. The knowledge of these valuable facts were obtained in no other way than those which the New York *Times* would make the butt of an inane and senseless joke.

It is only too unfortunate that it is a difficult task to impress upon the minds of the laity the importance of preventive medicine. One is reminded of the story of the ignorant Irishman, who, when during an epidemic of typhoid fever, was told that it was best to boil his drinking water in order to escape infection, and by so doing the germs which caused the disease would be killed, remarked "that he would just as lave make an aquarium out of his stomach as to use it as a morgue."

The editorial ends with the sage remark that "Man cannot evade microbes, however he may try." Surely the *Times* has not forgotten that the eradication of the various cholera and other epidemics that carried away so many of our forefathers was brought about by the discovery of the presence of germs on various sorts of articles brought to our shores from other lands. The *Times* would be one of the first to raise a hue and cry if the quarantine officers were to permit to pass through them a shipload of oranges coming from a port known to be infected with some contagious disease.

## DISEASES OF HOT CLIMATES.

Our comparatively recent acquisition of territory in the American and Eastern tropics gives us a renewed interest in the diseases that affect especially tropical regions. The English establishment of schools of tropical medicine is an index of the practical interest which this generation realizes must be taken in the special diseases of different and distant countries if sanitary measures are to make living in colonial regions any more wholesome than it has been in the past. There has come in recent years moreover the precious realization that the comparative study of the diseases of the different parts of the world may very well serve to throw light upon even the best known diseases in the ordinary conditions of the temperate zone. Besides, with the increase of commercial activity

at the beginning of the twentieth century quarantine is ever of more vital interest and tropical diseases are found not to be absolutely limited to very warm climates but occur sometimes under rather alarming circumstances in the temperate zones.

In recent years many of our large cities have had cases of the so-called sleeping sickness in their hospitals. This has sometimes been considered an affection limited to the negro race. It is evident, however, that symptomatic conditions resembling the so-called sleeping sickness of Africa may occur among other races and without the predisposing influence of a torrid climate. In his recent book on diseases of warm countries, Dr. Scheube, late professor of medicine and pathology at the medical school of Kioto, Japan, reviewing the literature of sleeping sickness, declares that in the few autopsies recorded the pathological condition has usually been a meningo-encephalitis. He adds that Mauthner suggests a relationship between sleeping sickness and Wernicke's acute polio-encephalitis superior.

Almost needless to say, bacteria have been found in some of these cases and have been declared specific by certain observers. In Africa, the disease seems to be limited to negroes. This is sometimes attributed to the fact that the lethargic condition which develops is only a small exaggeration of the ordinary condition of the negro in South Africa whenever he is asked to be quiet for a time. Missionaries tell that it is practically impossible to keep the South African negro awake for sermons and instructions and their only hope is to use the Socratic method and keep asking frequent questions. Portuguese observers have found a short bacillus which they declare to be the cause of the disease, but so far their discovery has not been confirmed by others. Manson believes that the condition is usually due to the presence of the *Filaria perstans*, a small blood, worm-like parasite that has been found in some of the cases in North Africa, especially along the Nile, though it does not seem to occur in the southern part. It is possible that some of these suggestions may be useful in leading American observers to the more careful investigation of some of the cases of continuous lethargy that are reported from time to time in this country.

With regard to the interesting oriental conditions known as running amok, or amuck, during which the subject of an attack usually runs wildly through the street brandishing firearm or saber and killing every one whom he can reach, the present generally accepted theory is much more satisfactory than some of those formerly suggested. The condition used to be attributed to the inordinate consumption of certain crazing drugs. There is no drug known in the East, however, that produces any such excitant effect. The condition is now recognized as a temporary mania on an epileptic basis and in a number of recent cases scars have been shown on the tongue demonstrating the occurrence of previous attacks of epilepsy. The condition then is only one of these epileptic states with homicidal tendencies which are noted in other countries and which are making the path of the medicolegal expert and the proper enforcement of laws with regard to murder when committed by epileptic patients ever more and more difficult.

The distribution of the ordinary infectious diseases in the tropics is extremely interesting. Whooping-cough, apt to be considered with us rather a disease of cold weather, early spring and late fall, is very frequent and very fatal among the South Sea Islanders. In 1883 3,000 Fijians were carried off by an epidemic of this disease that we are apt to call one of the ordinary children's diseases. The distribution of epidemic parotitis, mumps, and acute muscular rheumatism is exactly the same and they are rather rare diseases in the tropics. There is no acute rheumatic arthritis in Manila or Singapore. This is an interesting commentary perhaps on the bacillary origin of rheumatism and hints at the probable absence of the microbe of the disease as yet in these parts.

Smallpox becomes a veritable scourge in the tropics and, curiously enough, the protection afforded by vaccination is not near so long-lasting in warm climates as in temperate regions. This shows the need for warning those about to go to warm countries of the advisability of having their vaccination renewed. There has been a general impression growing of late years that vaccination can not be depended on to protect for as many years as used to be thought, when the epidemics of the disease are as virulent as those which usually occur in the tropics. Measles is very common and more fatal than in the temperate zones, showing that the so-called catching of cold or exposure to low temperature is not as serious a cause of fatal complication in measles as is sometimes thought. Scarlet fever is not endemic in the tropics at all. When cases of the disease are introduced from without it does not spread and, at most, affects only those who have been in intimate contact with the patient. The scarlet fever itself

soon dies out. This is a very curious and rather surprising observation and may lead to the finding of some reason for the anomaly due to some characteristic of the microbic cause of the disease which has not as yet been definitely recognized. It may also serve as a criterion of any announced bacterial causes of the disease somewhat as exposure to cold was used with regard to bacteria found in yellow fever cases. It will be remembered that Professor Vaughan, of Ann Arbor, used this test for the effective rejection of Sanarelli's supposed bacillus of yellow fever.

## ECHOES AND NEWS.

### NEW YORK.

**Babies en Voyage.**—The first trip for the season of St. John's Guild Floating Hospital took place last week. The boat left the foot of West Fiftieth street with 338 people on board, including 78 babies. The boat then made stops at West Thirty-fifth street and West Tenth street, where 600 more passengers were taken on board. The boat proceeded down the bay and off New Dorp landed the children who were very ill, at the Seaside Hospital of the Guild. The Guild will operate only one boat this year, owing to lack of sufficient funds. John P. Faure, former Commissioner of Charities, who is in charge of the trips, said that more funds were needed for the work. Since last year the boat has been fitted with wards for dispensary service, and there is also a quarantine for contagious diseases on the upper deck.

**Program of the Summer School in Philanthropic Work.**—The sixth annual session, commencing June 22 and extending to July 31, 1903, is now in progress, being conducted by the Charity Organization Society of the City of New York, of which Philip W. Ayres is director. Dr. Silas F. Hallock, of New York, will be in charge of the meetings devoted to medical charities, for which four days will be allowed, as follows: Thursday, July 16—The management of contagious diseases in New York. Dr. William Hallock Park of the New York Municipal Laboratory; Friday, July 17—What the Charity Worker Should Know of the Treatment and Prevention of Tuberculosis. S. A. Knopf, M.D., New York; Saturday, July 18—Social Factors in the Prevalence of Consumption. Miss Lilian Brandt, statistician of the Committee on the Prevention of Tuberculosis, Charity Organization Society; Monday, July 20—The Problem of Caring for Children in Institutions. Mr. R. R. Reeder, superintendent of the New York Orphan Asylum. This subject naturally falls in the preceding section, but it is treated at this time because Mr. Reeder cannot be present on the earlier date; Tuesday, July 21—If the conditions permit, Dr. Alvah Doty, health officer of the Port of New York, will take the members of the school to visit the quarantine station and explain its work.

**A New Hospital Opened.**—Commissioner Folks of the Department of Public Charities announces that he has opened on Blackwell's Island a new hospital for convalescent patients under the jurisdiction of his department. "The object of the Hospital for Convalescents," he says, "is to aid patients in their quick recovery. It is the purpose to admit patients who can be brought back to a useful life by a few weeks of rest with healthful surroundings, good treatment, and nourishing food. Chronic, contagious, and incurable diseases will not be received. Patients will ordinarily be allowed to remain for a period not exceeding three weeks, but special cases may remain six weeks if approved by the resident chief of staff. Heretofore, there has been no public institution of this kind in New York city, and the result has been that frequently patients, after an acute disease or surgical operation, were forced to leave the city hospitals, to provide room for emergency cases, in a state that often produced great injury to themselves. The need for such a hospital has been strongly urged by charitable societies and philanthropists for some years. The hospital is in the building formerly occupied by the Manhattan State Hospital, now the property of the Metropolitan Hospital on Blackwell's Island. It has been altered and repaired at a cost of $17,500, to fit it for its present use. It is situated on the northern end of Blackwell's Island, facing the grounds of the Metropolitan Hospital on one side and the East River on its rear. The present capacity is 40 beds for men and 30 for women. It will be increased as needed to about 70 beds for men and 60 for women."

### PHILADELPHIA.

**Dr. Gibbon on Pennsylvania Hospital Staff.**—The vacancy on the surgical staff of the Pennsylvania Hospital caused by the death of Dr. Thomas G. Morton has been filled by the appointment of Dr. John H. Gibbon. The appointment was made from among a dozen of surgeons applying for the position. Dr. Gibbon was last year elected professor of surgery at the Philadelphia Polyclinic.

**Change in the Board of Health.**—The places of two of the lay members of the Board of Health have been filled, as their terms expired, by the appointment of Dr. Charles B. Penrose and Dr. Leonard Pearson. Dr. Penrose was formerly a professor at the University of Pennsylvania and Dr. Pearson is at the head of the Veterinary Department of that institution. The appointments are in line with other actions of Director Martin who is surrounding himself with advisors and assistants who are especially adapted to fill their positions.

**Dr. Pearce Goes to Albany.**—Dr. R. M. Pearce, Assistant in the Pathological Department of the University of Pennsylvania, has been elected Professor of Pathology in the Albany Medical College and Director of the Bender Institute of Pathology, Albany, N. Y. Dr. Pearce will have as assistants Dr. E. M. Stanton of New York and Dr. Charles K. Winne of Mount Wilson, Md.

**Paid Medical Inspectors a Possibility.**—Representatives of the Public Education Association have petitioned Director Martin for a corps of paid medical inspectors of public schools. Dr. Martin is in thorough accord with the plan, and is in favor of an appropriation of $100,000 for the employment of 130 inspectors at a salary of $75 for each school month of the year. The volunteer force from January to September of last year discovered 3,446 cases of contagious diseases and 2,430 cases of non-contagious diseases among the school children of the city, but it is believed that much better work would be done under a system of paid inspection.

**Dentists Sentenced for Conspiracy.**—George C. Courtright, President of the Alba Dental Company, has been sentenced to one year and Dr. William Powell, manager, to three months' imprisonment,

because of conspiracy to defraud. A dental student employed by the firm, broke the jaw of a person applying for treatment, and suit was brought against the company for employing unregistered assistants. Courtright, although not a graduate of any dental college, admitted that he was called "Doctor" by his employes and had the professional title printed on his cards. It is said that several prominent dentists and the faculties of local dental colleges were also interested in the prosecution.

**Hospital Plans Halted.**—Work on the proposed buildings for the indigent and the insane of Philadelphia has been ordered suspended. If Councils approve the plans of the new Director, larger sites, distinct from each other, will be sought probably in Bucks and Montgomery counties. As planned at first the buildings have together only 100 acres. The projected buildings will have from 600 to 1,000 acres each as grounds and the buildings will be planned so that they may be added to from time to time. The new plans have in view the outdoor recreation and employment of the inmates of the institution.

**Pennsylvania University Selects Dr. A. J. Smith for Professor of Pathology.**—The Trustees of the University of Pennsylvania, at their meeting last Wednesday, unanimously chose Dr. Allen J. Smith, of the University of Texas, to be professor of pathology to fill the vacancy caused by the resignation of Prof. Simon D. Flexner, who goes to the Rockefeller Institute for the study of bacteriology in New York. Dr. Smith is professor of pathology in the Medical Department of the Texas University and is also Dean of the Medical Department.

**Preparatory Course for Nurses.**—At the solicitation of Dr. S. Weir Mitchell and the superintendents of the leading nurses' training schools in Philadelphia, the Drexel Institute has undertaken to organize a Preparatory Course of Instruction for Nurses, under most competent instructors. Fee is $30 per term, there being two terms in the year, beginning respectively, September, 1903, and February, 1904.

## CHICAGO.

**Enforce the New Milk Ordinance.**—The passage of the new milk ordinance, which embodies stringent regulations for insuring pure milk for Chicago, marks an important extension of the health bureau's authority over the milk supply. The Health Department has been greatly hampered by lack of funds and uncertain milk supply. The inspection has been inadequate, and much impure and adulterated milk has been marketed in the city. The greatest imposition upon the poor was the sale of "skimmed milk" as whole milk, a traffic that yielded large profits to dealers. Tempted by the lower prices, the poor purchased it in ignorance of the fact that it was not only absolutely lacking in nourishment, but that it gradually starved babies fed upon it into disease. As milk is the staple article of food for the young as well as for many classes of invalids, its purity is a matter vitally related to the public health.

**Nathan Straus Pasteurizing Plant.**—Nathan Straus arrived in Chicago a few days ago to supervise the work of installing the Pasteurizing plant which he has donated to the Children's Hospital Society of Chicago. Work on the plant is progressing so rapidly that the distribution of milk probably will be begun within a week. Fifteen branch stations will be established, and many thousands of families will be supplied from them. Circulars have been sent out explaining the enterprise, and the milk commission of the society is seeking contributions of $5,000 to carry on the work.

**Nurses Graduate.**—Eighteen nurses graduated from Mercy Hospital Training School June 30. Professor N. S. Davis, Jr., addressed the graduating class.

**Reopening of Lincoln Park Sanitarium for Sick Babies.**—This Sanitarium has just begun its seventeenth successive season. During the fifty-nine days in which the Sanitarium was open in 1902, more than 35,300 children and 45,440 visitors were received at the institution. Of the children, 7,249 were sick babies, attended by mothers, who in many cases were quite as ill and helpless as the little ones. Persistent course treatment was administered to 1,690 sick children.

**Mortality Statistics.**—Notwithstanding the favorable showing of general mortality, the deaths from contagious diseases of childhood—notably diphtheria—remain distressingly high. The steadily increasing mortality of diphtheria is nothing short of a reproach to the medical profession. The value of antitoxin, both as a curative and as a preventive, has been demonstrated as no other medicinal agent ever has. And yet within the week the death is reported of the wife of a physician after but a few days' illness of diphtheria. The doctor himself was also stricken. Antitoxin, in full strength and quantity, never yet failed to cure a case of diphtheria when administered on the first day of the disease, and but rarely when on the second or third days. Just as certainly, when administered within even three days after exposure to a case, it will prevent contracting the deadly disease. In every case of suspicious sore throat, antitoxin should be given at once and in large amount. It can do no possible harm if the disease should prove not to be diphtheria; it will save life in 99 cases out of a hundred, if it be diphtheria.

## GENERAL.

**Alcoholism in Belgium.**—Recent investigations show that there is one liquor saloon to every 36 inhabitants in Belgium; this proportion outnumbering that of France where it is one to 75 inhabitants, England 1 to 82, Prussia 1 to 100, Austria 1 to 200 and Russia 1 to 991.

**The Fifth International Congress of Dermatology.** This Congress will be held in Berlin September 13 to 17, 1904. Subjects for discussion will be: (1) Syphilitic Affections of the Circulatory System. (2) Cutaneous Affections and Their Relation to Disorders of Nutrition. (3) Epithelioma and Its Treatment.

**The Special Senses of Animals.**—Dr. Werner, of Vienna, has lately printed the results of his observations upon the special senses of animals, especially upon the senses of reptiles and amphibians. He concludes that these latter are capable of going directly toward water, which attracts them, so to say, even at long distances. Light acts upon them, independently of heat. In winter they quit warm lairs to go to sunlight. Their sight is generally good and is probably their most acute sense; yet their vision is very limited. Crocodiles cannot distinguish a man at distances above ten times their length. Fish see for only short distances. The vision of serpents is poor. The boa-constrictor, for example, can see no further than a third of its own length. Some snakes see no further than one-eighth of their length. Frogs are better endowed and see twenty times their length. The hearing of all these animals is even worse than their sight. Most rep-

tiles are deaf, especially boa-constrictors. "Deaf as an adder" may represent a careful observation of our ancestors.

**Tuberculosis Sanatorium.**—Dr. F. M. Pottenger is building a sanatorium for tuberculous patients at Monrovia, California, sixteen miles east of Los Angeles at the foot of the Sierra Madre mountains. The site of the sanatorium is on an elevation above the town at an altitude of about one thousand feet. All of the rooms will face south, and from them can be obtained a view of the San Gabriel Valley for nearly fifty miles with Catalina Island, sixty miles away, plainly visible on clear days. The capacity of the institution will be about fifty patients, only the administration building, with a few rooms, will be built this summer.

**Regulation Affecting Post-Office Physicians.**—Postmaster-General Payne on July 1 issued an order abolishing the position of physician in post offices at the close of business June 30, 1903. This order wipes out a small list of officials whose employment without specific authority of law has caused wide discussion in connection with the Post Office investigation. Some of these offices paid $1,700 a year. The post offices employing physicians up to the close of the fiscal year, when the Postmaster General's order took effect, are New York, Chicago, Brooklyn, Philadelphia, and Boston.

**Obituary.**—Dr. Charles Lancaster, ninety-five years old, a well-known physician, lawyer and literary man, died last week in Plainfield, N. J. He was born in East Winthrop, Me., and early in life was intimately acquainted with Emerson and Longfellow. He was a talented writer, and entered the medical profession and practised for many years. He was the author of many newspaper and magazine articles and wrote several text-books. He lived at one time in Philadelphia and came to Plainfield in 1895.

## CORRESPONDENCE.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

London, June 27.

BIRTHDAY HONORS—THE ROYAL FAMILY AND THE MEDICAL PROFESSION—RETIREMENT OF SIR FREDERICK TREVES.

The list of "Birthday Honors," as they are called, which was published yesterday contains the names of several members of the medical profession. By far the most distinguished of them is Dr. Manson, whose name is so closely and so honorably associated with the establishment of the mosquito theory of malaria. He is now "Sir Patrick" and his wife is transfigured into Lady Manson. Manson has not only been a pioneer in research, but he has been the initiator of the movement in this country for the special study of tropical diseases. The London School of Tropical Medicine is his creation. He is Medical Adviser to the Colonial Office, and he has used the opportunities afforded by his position to impress on Mr. Chamberlain the vast importance, from the point of view of the expansion of the Empire, of finding means to protect colonists against tropical diseases. This is frankly acknowledged by Mr. Chamberlain himself in a parliamentary paper recently issued, in which the work done by the Schools of London and Liverpool and by scientific expeditions sent out to West Africa, the West Indies and elsewhere, is set forth in detail. Manson's work entitles him to the gratitude of the human race, but he would have had long to wait for recognition had he not held an important office under a statesman whose influence is paramount.

Another physician who exchanges the title of "Dr." for that of "Sir" is Stephen Mackenzie, a younger brother of Sir Morell Mackenzie, whose attendance on the Emperor Frederick has made him a historic character. Sir Stephen Mackenzie is an excellent all-round physician who has never stooped to court the favor of the public by any kind of advertisement. The unpopularity of his brother, to whom he was under great obligations, made his path particularly arduous, but he conquered by sheer straightforwardness. He is the senior physician to the London Hospital, an institution which has of late basked in the sunshine of royal favor. This is partly due to the interest taken by the Queen in the light treatment introduced by her countryman, Finsen. The London Hospital was the first in this country to make provision for the application of this method, and the Queen presented it with some lamps for the purpose. Adroit use has been made of this act of royal beneficence by the Chairman of Governors, Mr. Sydney Holland, himself the grandson of a well-known physician, Sir Henry Holland, who married the daughter of Sydney Smith; and the London Hospital is reaping the reward of clever appeals to the instinct which is strongest in the British breast—that of loyalty.

Knighthoods are also conferred on Mr. A. D. Fripp, who found fame and fortune in a wound made on the person of a princeling by a poisoned shaft from Cupid's bow; on Dr. Perry of Guy's Hospital, who is the leading spirit on the Advisory Board of the Army Medical Service; and on Dr. P. Heron Watson, Surgeon to the King in Scotland. A number of decorations also fall to the share of senior medical officers of the Army. There is no name of any special distinction among them; they are like *fortisque Gyas fortisque Cloanthus* among the followers of Æneas.

The King, who is an Honorary Fellow of the College of Physicians and Surgeons, is fairly orthodox in his medical belief. Even before his attack of appendicitis he took an interest in that important department of surgery which takes not the vermiform, but another appendix, for its province. At any rate he has been known to criticize with severity the treatment adopted by eminent surgeons of certain disorders which, *consule Planco*, were rather common among the noble lords who deemed it a privilege to be his lackeys. But in medicine the Queen has a distinct leaning to heretical doctrines. Some time ago when a few homeopaths were getting up a memorial to one of the number, Mrs. Clarke, the wife of Dr. John H. Clarke, editor of *The Homeopathic World*, asked for a subscription from Her Most Gracious Majesty, on the ground that "Mrs. Clarke believes that Her Majesty has taken an interest in homeopathic practice and trusts that the foundation of the British Homeopathic Association, under the presidency of Earl Cawdor, for establishing a School of Homeopathy, so much needed in London, will meet with Her Majesty's sympathy." Whether it did so or not, I am unable to say. The Queen's name does not figure in the subscription list, but an awkward situation would be produced if the Queen went out of her way to express publicly her sympathy with an unimportant sect. The position is somewhat akin to that of Lord Chancellor Thurlow when he was asked by some Noncomformist divines to remove the disabilities under which they then labored. He replied, "Gentlemen, I can do nothing for you. The Church of England is established by law in this country. You get your d—d religion established and I will do anything you like." Orthodox medicine is "established" in this country and medical noncomformity cannot, therefore, be openly recognized by royalty. As an illustration of their position I may mention that

it is perfectly well known that they one and all cordially detest vivisection, but they do not dare to say so.

In connection with the relations of the royal family to medicine and its professors, I may take this opportunity of pointing out that a story told in your columns, in the issue of March 28, about Sir Richard Douglas Powell, is quite a curiosity of inaccuracy. That eminent physician who is said to be "well known for his bluntness" is represented as speaking with remarkable plainness to the King and as replying to the remonstrances of Sir Francis Laking with a declaration that if there was to be any "squirming" Laking must do it. Laking is indeed a first class "squirmer" and is known among his friends as the "Medical diplomat." But Douglas Powell is the very opposite of blunt; he has the bland unctuousness of manner as he has the solemn appearance of an ecclesiastical dignitary. He takes himself and everything that he does very seriously indeed. He talks like Sir Oracle, whom no dog's bark should be suffered to interrupt. The stories related of him by your contributor would fit the late Sir William Jenner who, though trusted by Queen Victoria, was disliked by the present King for his plainness of speech. But Sir Richard Douglas Powell would think it blasphemy to be accused of the language put into his mouth.

Sir Frederick Treves has just intimated his intention of retiring from practice at the end of July, that is, at the end of the London season. He is a man in the prime of life and in full vigor of mind and body; he is also at the highest point of what economists would call his productiveness. His determination has therefore caused no little surprise among his professional brethren, though I have no doubt it will be highly approved by those of them who make a specialty of abdominal surgery. I do not know what may be the true inwardness of the retirement of the most successful surgeon in Great Britain at the very height of his popularity. It is not ill-health, for he means to continue his work as a member of the Advisory Board of the Army Medical Service. It is probably a natural desire for rest after twenty-five years of exceptionally exacting work. Few men have worked harder than Treves. Last week he performed ten abdominal sections, and I have been told by one who knows him well that since the operation on the King he has been so overwhelmed by the crowd of patients that there have been days when, if he had had the time, he might have done fifteen operations between sunrise and sundown. He has, of course, made a considerable "pile," and he has no family now depending on him, one of his daughters having died soon after his return from South Africa, while the other was married within a week or two of the historic operation at Buckingham Palace. It has been said that he has an ambition to win fresh distinction in political life, but this he positively denies. It is tolerably certain, however, that he will be heard of again. His retirement may turn out to be like that of Gladstone who, after playing Cincinnatus for a few years, came from his cabbage garden to take the head of his party. It is at any rate to be hoped that Treves will, for the benefit of science and mankind, gather the fruits of his unrivaled experience into permanent shape.

**The Bactericidal Action of Human Blood-Serum.**—Experiments conducted with the blood serum of healthy human subjects have been made by E. LOWENSTEIN (Deut. Archiv f. klin. Med., Vol. 76, Nos. 1-3), in order to determine not only the actual bactericidal properties, but also whether there is any relation between this property and the course and severity of the disease. It was found that the serum of adults possesses strong bactericidal action when directed against typhoid bacilli and cholera vibrios, but only a weak action against anthrax.

## SOCIETY PROCEEDINGS.

### NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENITO-URINARY SURGERY.

*Stated Meeting, held April 15, 1903.*

John Van der Poel, M.D., Chairman.

**Gumma of the Lip.**—Dr. James Pedersen gave the history of a man, twenty-three years old, a cook by occupation, who was admitted to the hospital with an extensive ulceration involving the left half of the upper lip, extending into the mouth at the angle for some distance, and having a copious, fetid, purulent discharge.

Fig. 1.

Appearance on admission to the hospital.

It was a very unsightly condition. The absence of induration and of inflammatory thickening was marked. He was first admitted to Dr. Bryant's service with a tentative diagnosis of epithelioma; but was transferred to Dr. Bang's service and came under Dr. Pedersen's care. A history of an initial lesion eight months before was obtained. He was at once placed under antisyphilitic treatment. Later he was presented before two clinical societies; the diagnosis of epithelioma was made by some notwithstanding that the condition had

Fig. 2.

Gumma of the lip: after about two weeks of treatment.

improved under mercury and iodide of potash. Tuberculosis was easily excluded. Treatment by hypodermatic injections of mercury and increasing doses of iodide of potash had been followed by good results, improvement continuing progressively. When the patient left the hospital there remained only a small unhealed surface. The patient reported at his office once or twice after that. Dr. Pedersen thought it interesting to note that, in spite of the large ulcerating surface originally,

the resulting scar was not very perceptible and the deformity but trifling.

**Cyst of the Sheath of the Penis.**—Dr. James Pedersen related the history of a man who was admitted to the hospital in November, 1902, with the following history: He had had no venereal disease. About eight months before admission he had been struck on the left side of the penis by a baseball. The spot became painful but no swelling occurred until two months after the receipt of the blow; this swelling was dark-blue in color and not very painful. The patient squeezed it vigorously on several occasions in attempting to force the contents out. Finally he succeeded, the rupture taking place at the free border of the prepuce. A thick dark brown material was discharged. The sac soon refilled. One month prior to coming to the hospital, a physician made a small incision at the summit of the swelling. A discharge of pus was said to have occurred. Examination showed a firm ovoid mass apparently attached to the corpus cavernosum having, at its summit,

Fig. 3.

Cyst of sheath of penis.

a crater-like depression, where the small incision had been made. During the succeeding night the sac ruptured at this point and the contents were lost in the dressings. In consequence, at the time of operation, the mass was found considerably reduced in size. The probable nature of the contents was not recorded. An elliptical incision was made and the sac everywhere carefully dissected out and trimmed off down to its floor, which seemed to blend with the fibrous sheath of the corpus cavernosum. No attempt was made to remove the floor because of the risk of producing a contracting scar in the sheath of the corpus cavernosum. The floor was thoroughly scraped with a sharp curette and the skin brought together over it. Primary union was obtained except at one angle from which a scanty serous discharge took place until after a few injections of a stimulating silver nitrate solution. When last seen the patient said erections occurred without pain or curvature and that he could now cohabit with comfort. His chief complaint has been that because of the mass he had not been able to cohabit. The walls of the sac, which were about one-eighth of an inch thick, were examined and found to consist of dense fibrous tissue.

**An Unusual Case of Peri-urethral Abscess.**—Dr. Howard Lilienthal presented this patient, a man, thirty years old, who had been sent to his service at the Mt. Sinai Hospital February 22. When he entered the hospital his principal complaint was pain and induration in the testicle. His family history was negative. He had gonorrhea eight years ago and this was accompanied with joint swelling and other symptoms for two months and an intercurrent attack of pneumonia. He had a gonorrheal discharge for seven months and then it ceased. His present illness began with his second attack of gonorrhea which he had last February. Three weeks before admission he noticed a swelling in the midline of the penoscrotal junction which was hot and tender. He had also a certain amount of chordee. One week before the operation he had this abscess incised by Dr. Goldenberg. A careful examination of the pus by culture and spread showed it to be sterile. On admission his purulent discharge from the urethra did not contain gonococci. The mass at the penoscrotal junction was indurated, and was about 5 cm. in diameter extending to the left side. At its center was a sinus through which a probe could be passed for a distance of about six or seven inches upward into the left groin. No organisms could be found by culture or spread from the discharge from the sinus. The upper pole of the epididymis was tender and enlarged. The inguinal glands on the left side were more enlarged and tender than on the right. Operation was performed on November 28. This patient had been thought to be tuberculous and had been given an iodoform-glycerine emulsion by injections which did him no good. The reason he was thought to have tuberculosis was because no findings by culture or spread were obtained. He opened the left tunica vaginalis but he did not find it necessary to go far up into the groin because the channel had partly closed. He had great difficulty in tracing the pus to its source but finally succeeded after a very extensive operation: it was in the neighborhood of the urethra near the penoscrotal junction. By the aid of retractors he opened down to the bottom and scraped it out thoroughly and packed it with iodoform gauze. A very amusing incident occurred at the time of operation. There were a great many indurated masses in the tract and, wondering what the disease was, the doctor excised some of the yellow granular deposits with the idea that the case might be one of actinomycosis. When he recalled the injections of iodoform-glycerine emulsions these deposits were explained. There was so much of the tunica vaginalis involved that he removed the thickened portion and left the testicle pretty well uncovered. It was noted that on March 18 the discharge from the urethra continued but no organisms were found in it. On April 2 the sinus was curetted and packed with iodoform gauze. April 10 there was no discharge from the urethra although the patient was still receiving urethral irrigations. The patient was in the hospital at present being treated for a small sinus which persists and may have to be again curetted.

Dr. Ferd. C. Valentine asked if it was Dr. Lilienthal's experience, dealing with peri-urethral abscesses to have fistulæ remain, especially in those cases which resulted from breaking down of infiltrated glands. At present he had several such cases. In these he used the Kollmann galvanocaustic needle to destroy the cicatricial tissue which lined the fistulæ; adhesions then formed and no disagreeable results supervened. He referred only to those smaller fistulæ which connect with the urethra and whose extent was too small to warrant plastic operation.

Dr. F. Tilden Brown asked Dr. Lilienthal where the starting point of this sinus was situated and also what was the probable etiology of the condition.

Dr. Howard Lilienthal said that he had seen fistulæ which were said to be the result of peri-urethral abscesses and he had operated upon them, but it had been his fortune thus far not to have had fistula result in any case that he had operated upon. Still they continued to come into the hospital with fistulæ. Rather than to evacuate the abscess into the urethra he thought it better to open it early from the outside for the reason that these fistulæ occur on account of the necrosis of a considerable part of the mucous membrane of the urethra itself and these fistulæ were more likely to occur if you allowed them to break spontaneously into the urethra. He advised operating from without so soon as you are sure that you are dealing with a peri-urethral abscess. Of course there will be a minute opening between the urethra and the abscess cavity but that will take care of itself.

He said that the origin of this abscess was at the penoscrotal junction and originated in all probability from a peri-urethral abscess gonorrheal in character.

Dr. John Van der Poel said that in five or six cases of peri-urethral abscess he had been unable to find gonococci or other bacteria in the pus. In each of these instances by means of the endoscope he had been unable to find any trace of an urethral opening to the abscess, but in other cases when there was a urethral sinus, gonococci had been found in the pus passed from the abscess cavity into the urethra, and collected in the endoscopic tube.

**Rupture of the Urethra.**—Dr. J. A. Bodine reported the history of a man, fifty-six years old, who had sustained subcutaneous rupture of the urethra as the result of falling astride an iron beam. He felt dazed for a time, but resumed his work. He noticed moisture at the meatus and on examination found blood issuing. He went to Long Island City and called his physician. There was no desire to pass water, although the patient was sure he had not urinated since early in the morning. His physician wisely attempted no instrumentation except to pass a soft catheter which stopped at the membranous urethra. Patient was sent into St. John's Hospital the evening of the same day and operated upon eleven hours after the accident. Blood was flowing from the meatus and a scrotal hematoma the size of a fetal head existed. The perineum was distended, fluctuant and ecchymotic. A sound introduced through the meatus was arrested in the membranous urethra, its tip lying just under the skin of the perineum. Incision through the skin showed the muscles to be extensively lacerated and torn. There was considerable active bleeding, which was easily controlled. No infiltration of urine had occurred, though the bladder was very much extended. There was no deep urethra present. A finger could be passed directly up to the subpubic arch. The torn proximal end could not be readily found, though little time was spent in its search as the distended bladder above the pubes offered such an easy and rapid method of identification by a suprapubic puncture and retrograde catheterization. The segments of torn urethra were identified, and as they could be approximated without tension, were sewn together around a soft catheter, introduced through the meatus. The perineal wound in the muscles was left open and packed with gauze. The suprapubic wound was sutured, both the bladder and abdominal wall, except its lower angle, through which issued a silk thread the other end passing through the eye and lumen of the catheter out of the meatus. The bladder was drained through the urethra for ten days. Daily withdrawal, sterilization and reinsertion of catheter being practised. Primary union of urethra occurred and the patient left the hospital in four weeks. No leakage of urine through perineal wound could be detected. A No. 30 French sound passes without any inconvenience, the urinary and sexual functions were perfect. The inducement to do suture of the entire circumference of the urethra around the catheter in an effort to secure primary union were the absence of any urinary extravasation in the perineum and the lack of tension when the torn urethra was approximated. He emphasized the value of suprapubic puncture with retrograde catheterization as the easiest and quickest method of identifying the proximal end of the torn urethra.

Dr. Howard Lilienthal believed that the suprapubic operation was the only thing to do in such a case. He had seen valuable time wasted in attempts to reach the posterior urethra when it could be readily managed by making a suprapubic opening. He thought Dr. Bodine would have taken fewer chances had he drained the bladder through the suprapubic wound.

Dr. F. Tilden Brown reported a case seen two weeks ago which demonstrated the utility of the suprapubic opening. During the operation he wished to have a leading thread in order that he might introduce a larger catheter. After he had made his suprapubic incision a soft catheter was passed through the proximal section of the urethra; the distal or eye-end of the catheter in the bladder had passed over it a loop of silk. He expected to use this silk thread to bring a larger catheter in. This was deemed important because of the existence of a tight stricture in the anterior urethra and because the rupture was the result of the necrotic state of the membranous urethra secondary to extravasation of urine; there were present numerous fistulous tracts also. This man passed his urine through the perineal opening and since operation he has been able, by the aid of vision and touch, to pass a sound into the posterior urethra. The first time he attempted this the vesical end was well out of sight and it was difficult to see whether the point of the sound traveled the proper course. To act as a safeguard he passed a curved catheter into the perineum.

Dr. Pedersen said that formerly much damage had been done by overzealous attempts to pass a catheter. It was reassuring to note that a better understanding of these cases was becoming established among practitioners in general. In these cases the urethra should not be explored until preparations for operating had been completed, and the operation should be undertaken as soon as possible.

Dr. J. A. Bodine said that the suprapubic wound was closed by suture, except its lower angle. The attachment of a silk string to the end of the catheter in the bladder bringing the other end of string out of the open lower angle of suprapubic wound insured an easy and safe reinsertion when the catheter was withdrawn for sterilization. He asked the members present if they frequently had delirium associated with suprapubic operations on the bladder. Delirium followed in this case and he thought it was due to absorption of urine through the wounded surfaces, though the wounds were clean and there was no escape of urine through the perineal section. The quantity of urine and percentage of urea were normal. It had been his experience that delirium followed the suprapubic incision into the bladder in many cases. He recalled this annoying symptom in four prostatic operations where the incision had been made above the pubes.

Dr. Howard Lilienthal said he had performed many suprapubic operations for various reasons and had had only one case in which delirium occurred; this patient

had a severe hemorrhage and was septic and it was natural that delirium should follow. He had seen two cases of delirium following the suprapubic operation for stone. One terminated fatally, the other not. He could not explain the delirium occurring in Dr. Bodine's cases. He believed the suprapubic operation to be simpler than the perineal.

Regarding the thread he used silk thread that had been been dipped in compound tincture of benzoin; this made it not only aseptic but holds knots fast as well as rosin would.

Dr. F. Tilden Brown believed that it would have been a mistake to use an unreasonable ligature material in this patient because, unless the parts were kept open, the silk ligature would serve for granulations to grow upon. He preferred chromicized catgut to silk.

Dr. John Van der Poel said he had seen one case of delirium following suprapubic operation for stone. In this case there was a purulent bronchitis and considerable temperature following the use of ether. The delirium abated with the subsidence of the bronchitis and its accompanying fever.

Dr. F. Tilden Brown said that he believed a person could have a low grade cystitis following a urethritis contracted some time prior to the suprapubic operation, without any micro-organisms being present except those that were considered to be normal, and without any urinary symptoms at all. In such an instance he would not be surprised to find, upon opening into the cellular tissues about the bladder, some evidences of constitutional disturbance due to absorption, not of high grade, but a low septic process.

**The Treatment of Acute and Subacute Anterior Gonorrhea by Retrograde Injections of Stronger Solutions of Silver.**—Dr. Hermann G. Klotz read this paper. The principal features of this paper were published last summer in Vol. LXII of the *Archiv für Dermatologie*. From previous experiences with irrigation of the anterior urethra with solutions of bichloride of mercury, nitrate of silver, permanganate of potassium, etc., he had become convinced that the mucous membrane showed much less irritation subjective and objective when such solutions were allowed to flow through the urethra in a retrograde direction, that is, from the bulbus to the meatus, than when administered in the contrary direction from the meatus to the bulbus. The syringe he used for his injections was a somewhat enlarged edition of the old Braun's intra-uterine syringe; the opening in the tube was located in the side of a bulb at the end of the syringe, so that the fluid was not easily projected beyond this point of the syringe itself. Lubricated with the injection fluid (protargol, argonin, albargin) or some other lubricant, the point of the tube was carefully inserted within the orifice and quickly passed down to the bulbus, when the syringe was slowly emptied of its contents. The fluid was retained within the canal for two minutes or more. Eight or ten hours after the injection the patient should begin injections of some of the common antiseptics or astringent solutions. After four or five days the silver injections should be repeated and, at this time, the condition of the urethra warrants a stronger solution. Treatment was continued in this manner until the discharge disappeared when all injections were finally discontinued. Toward the end of the injections the test with beer or whisky was allowed. Whenever after a reasonable number of injections a cure or decided improvement had not been effected, an endoscopic examination would usually reveal some local condition which would explain the persistence of the trouble and require stronger local remedies. He next considered the question, under what conditions a gonorrhea might be considered cured. He believed that a cure should be conceded if the discharge and gonococci had entirely disappeared and did not return after all treatment had been discontinued for several weeks and the patient had resumed his usual mode of living, particularly in regard to sexual intercourse and alcoholic habits. As a symptom of the greatest importance he closely watched for the disappearance of every trace of cloudiness from the first portion of the urine, particularly of the morning urine even though some threads or filaments might remain. He did not think it was possible in all cases to remove these threads; the efforts to accomplish this object often did more harm than good, he did not believe the presence of these filaments were in the least injurious to the men themselves nor to the women with whom they had sexual intercourse, even though there be present a small number of pus cells beside epithelia, provided there were no gonococci found on repeated examinations.

From a previous experience in subacute cases he was ready to follow Von Sehlen's example, adopting his principles, but with some modifications. Instead of using the ordinary syringe he employed the one above referred to, so as to place the silver solution as far as possible beyond the infected region of the urethra, in recently infected cases about three inches from the meatus, in the more advanced ones as far as the bulbus. He did not think there was danger of carrying active gonococci into the deeper portions of the urethra. After removing the syringe he followed Von Sehlen's method. He first used solutions of nitrate of silver from one-tenth, later usually one-eighth per cent. and higher concentrations. Where the inflammation was very intense and the mucous membrane very sensitive he occasionally resorted to thallin in seven per cent solution. Of the various organic silver preparations he had had experience with argonin, protargol, less so with ichthargan and argentamin. Since 1901 he had become very well satisfied with albargin, and later experience had confirmed the favorable opinion of this drug, which was expressed in a paper published last fall (MEDICAL NEWS, Nov. 29, 1902). Argonin had been employed up to 10 per cent., protargol 2 per cent. to 4 per cent., albargin 1 per cent. to 5 per cent., ichthargan up to 2 per cent., argentamin (more in the later stages) from 5 per cent. to 10 per cent. equal to one-half per cent. to 1 per cent. nitrate of silver. He said that all the newer remedies caused an increase in inflammation and secretion, furnishing a more favorable condition for the development of the gonococci: therefore, he deemed it advisable to use some gonococcidal injection only at stated intervals to avoid cumulative irritation; in the interval, he administered astringent and antiseptic solutions, and the following was his favorite, and which he designated briefly as the B.P.Z. Injection:

| | | |
|---|---|---|
| ℞ Boric acid ..... | 1.5 | grams (24 grains). |
| Acetate of lead, | | |
| Sulphate of zinc, of | | |
| each ..... | 75 | centigrams (12 grains). |
| Glycerin ..... | 4 | grams (1 dram). |
| Water ..... | 120 | grams (4 ounces). |

M.S.

In general his experience had been that cases of gonorrhea which came under treatment soon after infection and immediately upon the appearance of the symptoms, were permanently cured within a few, six to eight, days. In other cases he did not succeed in removing the cocci, but the symptoms were quickly reduced to such a degree that the patients hardly experienced any trouble except that immediately connected with the treatment, and all graver complications were

avoided. The earlier the treatment was begun the more successful would it be. When a patient presented himself for treatment on the appearance of the first symptom, say four to seven days after infection in primary cases, thirty-six hours to three or four days in reinfected ones, after emptying the bladder, an injection of some silver solution is immediately made in the concentrations of one-eighth to one-fourth per cent. of the nitrate of silver, 2 per cent. of protargol, 1 per cent. of albargin, etc. This was deposited three or four inches from the meatus. A second injection was made of a stronger solution if the first did not cause any burning. After removing the syringe the fluid was so manipulated that it was distributed as much as possible over the mucous membrane. If the patient called in the morning he was advised to take the B.P.Z. solution before his evening meal and at bedtime. The next morning he received his second injection of silver and again on the third day, the B.P.Z. injections being repeated as on the first day. On the fourth day the astringent injections were repeated three times, on the fifth was given a silver injection, then the B.P.Z. injections were continued for forty-eight hours and, on the eighth day, after twenty-four hours' intermission of all treatment, another silver injection was made. Should the symptoms continue after the seventh or eighth day the silver injections should be continued at intervals of three or four days, as in the subacute cases. In the later stages he preferred nitrate of silver to the organic silver preparations.

Dr. George K. Swinburne said that he was almost entirely in accord with all that had been stated by the reader of the paper. Any one who had treated this disease must work out his own method. He had used in the past retrojections, but he now preferred other methods. He was glad to hear Dr. Klotz say what he did regarding the threads occurring in the urine in these patients; many of these individuals spend their entire time examining their own urine looking for these flakes, which they consider to be the disease itself. These flakes could be proven to be non-contagious. One could make the urine clear up after a week or ten days, but these threads would very soon return.

He said he had been for many years now observing the effects of treatment in cases of acute gonorrhea, more so than in the chronic cases. He first began in 1888 with Dr. Brewer, and learned his method of hot retrojections of bichloride at the Vanderbilt Clinic. When he came to have a clinic of his own he started in to study the disease itself, giving patients placebos. In order to make his studies complete, and to learn the value of internal medication, every other patient received some supposedly antigonorrheic mixture, the alternate patient receiving the placebo. The results obtained in both treatments were practically alike. In some cases the discharge ceased, after a longer or shorter time; in others it went on to a chronic condition. Before this he had found that, in using ordinary urethral irrigation of bichloride, the bladder could be irrigated from the meatus without a catheter; this was in 1888. Then he made further studies, stopping all internal medication, and tried local treatment with nitrate of silver in dilute solution at first and gradually increasing them. Later the two-per-cent. solutions were tried as an abortive means, but found to be too irritating and to be especially disastrous in primary cases. He then took up the permanganate of potassium irrigations, irrigating with a fountain syringe. He then tried argonal, then protargol, albargin, and other preparations. Of late he had been using exclusively the new salt of silver, argyrol, because it was entirely non-irritating, no matter what the percentage used. There was no question regarding the valuable results he had obtained with this drug.

He had seen a large number of primary cases early in the disease, and only during the past winter forty primary cases were under his care at one time, all being primary cases of gonorrhea, and they came to him during the first week. Of this forty, twenty came within forty-eight hours, and fifteen within twenty-four hours after the beginning of symptoms.

A great many cases stop treatment when the discharge stops and remain away until the discharge returns; therefore, when they return, the disease has invaded deeper portions of the canal, the urethral follicles may be involved, abscesses may form, epididymitis may develop, etc., all due to the fact that the patients stop treatment too soon, because of their ignorance of the disease.

Dr. James Pedersen said that he was familiar with the method of treatment by retro-injections, as applied to subacute and chronic urethritis, but he preferred to call them *instillations*. He was, however, opposed to the stronger solutions of silver nitrate, fearing the after-effects which the delicate mucous membrane of the urethra must receive from a two-per-cent. silver nitrate solution. He preferred the milder solutions, although the course of treatment was thereby prolonged. He believed that the ultimate result as to a cure was as good, and that the more remote effect upon the mucous membrane would be even better than when the stronger solutions were used.

Time and again, when making an endoscopic examination of patients who had come to him suffering from chronic urethritis, he had been struck by the cicatricial appearance of the urethra in general and of the anterior two or three inches in particular. Enquiry had always developed the fact that these patients had used or had been given an irritating injection—one that had caused a subsidence of the discharge very quickly, but had given rise also to considerable burning when in contact with the urethral mucous membrane. He recently had the opportunity of inspecting a urethra which had been the seat of repeated severe attacks of urethritis. This patient had refused local treatment for some reason, and had simply treated himself on the expectant plan. Endoscopic examination showed a practically normal urethral mucous membrane. Dr. Pedersen pleaded for the use of milder solutions, even though the treatment required a longer time to effect a cure, meaning by "cure" the restoration to a condition in which the patient may be conscientiously allowed to marry.

Dr. Ferd. C. Valentine said that it was not clear to him how retrograde injections could produce less objective and subjective symptoms than those conventionally employed. Persistently advocating, as he does, the irrigation treatment of gonorrhea, it seemed to him that the entrance of fluid into the urethra and the flow therefrom, by carefully administered irrigations, could under no circumstance produce objective or subjective disturbances. It seemed to the speaker a violation of surgical principles to introduce any rigid instrument into an inflamed area, especially an area so sensitive as the urethra. The speaker further asked the author whether one of the claims he made for the instrument was not really an objection to it, namely that the fluid carried by the instrument into the urethra could not be projected beyond its acorn. This, it appeared to the speaker, would inevitably carry before that acorn the elements of disease, and would distribute them along the regions not yet infected. Dr. Valentine said that in the light of his experience whisky was by no means as reliable an irritant as beer and carbonated beverages.

with which to demonstrate the presence of gonococci in apparently cured cases. He referred, in this connection, to another one of Dr. Klotz's brilliant papers, in which the author had shown how severely irritating to the urinary apparatus the use of carbonated drinks can become. On the contrary, even the abuse of whisky does not, in the speaker's experience, exercise such an irritating influence upon the urethral mucosa as do carbonated beverages. In referring to the proofs of cure, the speaker took exception to von Zehlen's statement that if the discharge ceases and the patient resumes his usual mode of living, and had no recurrence of the discharge within three weeks, then the patient was to be considered cured. The speaker pointed out the large number of men who are apparently cured from gonorrhea, and even years later infect their wives. Dr. Valentine insisted that in no case should a physician consent to a patient's marriage until the beer-test, irritation of the urethral mucosa with injections of nitrate of silver or mercuric bichloride, interrogation of the prostate and seminal vesicles, urethroscopy, and finally the condom-test had proven him to be absolutely free, as far as modern science allows us to decide, from ability to infect with gonococci. Even then, wisdom demands repeated examinations of urine passed perfectly clear, both microscopically and by cultures to prove that the urine does not carry gonococci from some part of the genito-urinary apparatus. In speaking of the retrograde injector from its mechanical viewpoint, he could not but felicitate Dr. Klotz upon the ingenious improvements he had made in the instrument; but he insisted that a retrograde flow of whatever medicating fluid was employed, he must adhere to the far greater value and safety of irrigations, which do not entail the introduction of any instrument into the acutely inflamed urethra. Dr. Valentine agreed with Dr. Pedersen regarding the keratosis of the urethral mucosa, which is often found after strong drugs have been injected into the channel. Regarding the use of drugs in irrigations, experience had taught him to vary them, while he still placed greatest reliance upon potassium permanganate irrigation. In concluding he referred to the possibilities of there being various forms of gonococci, some yielding to irrigations with one drug, others to irrigations with other solutions.

Dr. William J. Brunner said he was impressed with the short time required to effect a cure. It seemed to him that experiences of most men were contrary to that statement. Not only in private practice, but in hospital and dispensary practice the cases ran three, four, five, six or seven weeks, and even then one could not be sure of a cure being effected. Again he believed the character of the patients under treatment had much to do with the course of the disease, *i.e.*, their mode of life had much to do with the ultimate results of treatment. It was the experience of many that the so-called cures later found their way to other doctors.

Dr. Frederic Bierhoff fully realized that so long as there were several men working along one line of work in this specialty, there would be several methods of treating the same disease. At present he adhered to the irrigation method, as opposed to the instillation and injection methods. He had not had any opportunity of using and testing the method advocated by Dr. Klotz. He agreed with the statement that the sooner we began treatment of gonorrhea the better it would be for the patient, and the greater the chances for cure. Personally, he had had some experience with the so-called abortive treatment, the treatment advocated by Frank, of Berlin, and others, and he was perfectly satisfied with it. In some instances after but one application, when the patients present themselves within twenty-four hours after the suspicious intercourse, the gonorrhea would disappear and remain away. In other cases though, that presented themselves within a few days after the suspicious intercourse, the gonococci have disappeared after one application of the irrigation treatment advocated by Levine, the gonococci remained absent and the patients had been absolutely free from any discharge within forty-eight or seventy-two hours, and remained so even after the most rigid tests. In cases of subacute gonorrhea he had obtained satisfactory results from the irrigation treatment, employing the modern gonococcicide drugs. It was his experience with the use of these drugs in gonorrhea that where the gonococci persisted after the eighth day of treatment he would have to deal with inflamed glands, with prostatic involvement, etc. In a fairly large proportion of cases with clear urine it was his experience to find gonococci in the prostatic secretion. He thought it stood to reason, where such conditions were present, that the irrigation or instillation of drugs could not be of service in curing these patients. They must be treated by different methods. If there was any danger at all, there was danger in the too great tendency to schematize. When recurrences occurred he thought it was due to insufficient treatment. If the prostate was involved, he believed it was due to a pre-existing condition of congestion of posterior urethra and prostate. The patients should be instructed that when the gonococci were removed and remained away, and the discharge had been entirely removed, if there were minute filaments present in the first urine, and they were found to be composed of mucus or fibrous shreds, with epithelia and isolated leucocytes perhaps, there was no danger whatever. If there were present, however, a large percentage of leucocytes it meant involvement of the glands and then, as a rule, the proper treatment would remove them.

Dr. Walter C. Klotz said he had employed this treatment during the past year in 200 cases of gonorrhea and, judging from the records of these cases, the results had been very satisfactory. Although the solutions used were stronger than those recommended by other authors, the patients had rarely complained of severe burning or irritation. In only 5 per cent. or 6 per cent. of all cases had inflammation extended to the posterior urethra and only a few of the latter cases developed epididymitis during the course of the treatment. The time of treatment was comparatively a short one. In some of the cases with primary attacks, the results were somewhat disappointing. In all cases the subjective symptoms were greatly relieved and the discharge much diminished.

Dr. B. Lapowski said that he knew of no one method for stopping the discharge in urethritis of specific origin. The trouble was not so much in stopping the discharge in those patients who wished to get married, but to get rid of the filaments that were present in the urine. The important point to remember was that the urine was not clear, and the question then comes up, "Are there any gonococci in that urine?" Any method that can rid these patients of the gonococci is the right method, and any method that fails in this object is the wrong method. He asked why it was impossible for us to state positively that the prostate was unaffected, and that there were no gonococci present, even in those cases in which the urine is clear? When the prostate is affected he asked how one could arrive at the conclusion that such was the case? He said we could never reach the lateral portion of the prostate for purposes of examination, because it was embedded in the rectum and, if that portion was affected there was the seat of the disease and there were the gonococci. The

prostatic epithelial cells were linked; between the prolongations of the cells the fibers and muscles go in. When the muscle contracted the cells contracted to expel the pus, but the muscles were never contracted to such a degree as to expel the gonococci which were in the cells. He related the instance of a patient, seen by him eighteen months ago, who gave no gonorrheal history. In the semen there were no spermatozoa. There was a clear discharge of fluid, which he could not tell whether it was prostatic or not. He asked for a specimen obtained after coitus. In natural coitus he said the muscles would contract nicely and press out the contents of the prostate; but when the coitus was not natural the contents would not be pressed out. This he considered to be a very important point. If such a patient married the following day often the gonococci would show themselves. He said that one should not forget the fact that there were other cocci present which looked like the gonococci and stained with Gram's stain and which were diplococci. Therefore, when one examines such a patient and finds something which looked like the gonococci and took the Gram's stain, often the conclusion was jumped at that it was gonorrheal. Some of these cocci were anaerobic and others aerobic.

He did not believe, as had been stated, that there were different kinds of gonococci, although they might act differently. One might be grown by agar-agar cultures and another might grow upon serum cultures. If a gonococcus be taken which had no vitality and placed in agar-agar serum for a long time, we may get a plain culture. A gonococcus may be had from a woman which has no vitality; and when transplanted to new soil it may develop. He believed that if we left the patients alone, only tending to the cleansing and keeping the parts at rest, we may hope that Nature itself will do something for the gonococci without our further help.

Dr. T. M. Townsend said that the larger number of gonorrheas he had observed, had readily extended to the prostate. He, therefore, could not speak favorably of retrograde injections of the anterior urethra. He believed from many clinical observations, that the selection of the medicament formed a potent factor in the rapid cure of the disease. He observed rapid and satisfactory results from intravesical irrigations of silver salts, especially albargin 1 to 2,000 following massage, in subacute follicular prostatitis, and concludes that this agent is of most service when gonococci becomes scanty and individual. Argyrol had not given him the results which its preliminary reports promised, though it proved the least irritating of the remedies that are offered as gonococcides.

## SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

*Meeting of May 6, 1903.*

The President, Robert T. Morris, M.D., in the Chair.

**Left Nephrectomy and Right Nephrolithotomy on the Same Patient.**—Dr. John F. Erdmann reported this case, and exhibited the patient showing the long vertical incision for the former, and the long oblique incision for the latter operation. The patient was thirty-one years of age, had been married fourteen years and had suffered several attacks of colicky pain, the last one being severe and characterized by a pain radiating to the side and extending down to the genitals. The patient had previously passed several small calculi. On incision of the transversalis fascia eight ounces of turbid, semi-purulent fluid escaped. The cavity was washed out with normal saline solution. Each operation took about forty minutes. Twenty-one small stones, weighing five grains, and one large one, weighing three drams, were removed from the pelvis of the kidney. An X-ray photograph taken by Mr. Caldwell showed the position of the calculus. Convalescence was assured after the first day. The chemical analysis, made by Prof. Mandl, showed an excess of uric acid and small quantities of calcium and magnesium phosphate.

**Notes on Torticollis.**—Dr. L. W. Hubbard presented this paper. He said that in considering the question of torticollis from the surgical standpoint it must be looked upon, not as a matter of life and death, but as a condition demanding relief because of the deformity. Torticollis might be defined as a contraction of certain muscles, usually the sternomastoid, but sometimes other muscles, along with the fascia and subcutaneous tissues. There was much difference of opinion expressed in the literature as to the frequency of torticollis. The two chief varieties were the congenital and the acquired. Out of 500 cases, seen at the Hospital for Ruptured and Crippled, 87 were congenital, a fact which seemed to bear out the author's opinion that there was a much larger proportion of congenital cases than was generally supposed. For some time Stromeyer's theory as to the cause of this form had been accepted, *i.e.*, that a rupture of the affected muscle occurred during delivery, most of these cases being breech presentations, but at the present time the prevailing opinion was that the cause of torticollis was to be sought in some prenatal condition, such as inflammation of the muscle and fascia. The acquired form was conveniently subdivided into the acute, the chronic and the spasmodic variety. In some instances torticollis developed years after birth, making this condition analogous to clubfoot. The characteristic deformity was a turning of the chin *away* from the contracted muscle, a point of diagnostic importance, for, by its aid, one was enabled to differentiate torticollis from cervical Pott's disease. In the latter the chin turned toward the contracted muscle, and there were pain and muscular spasm. Certain forms of torticollis, due to rheumatism, enlargement of the cervical glands and other causes, yielded readily to treatment on the removal of the cause.

The treatment was worthy of careful consideration, though there seemed to be a reluctance to recognize the importance of early treatment. A case was cited in which a young girl with a simple curvature was treated unavailingly by means of exercises, with the result that there was marked deformity. These cases should be subjected to treatment as soon as diagnosticated. Up to the sixteenth century no treatment had been employed except splints. In 1639 the first operation for torticollis was performed; later on Dupuytren practised subcutaneous tenotomy, a method even now employed by some surgeons. In doing this operation the vessels and subcutaneous tissues were liable to be injured, and on this account Dr. Hubbard thought the open method was more scientific. He advocated making a linear incision of sufficient size to thoroughly expose the fascia and muscle, and then dividing every contracted tissue. Primary union generally followed, and only a slight scar was left. The head should be kept in proper position until union had taken place. It was better to do the operation under general anesthesia, but he had operated under cocain anesthesia. The first case operated upon was that of a woman of twenty-nine years in whom the deformity had existed since birth. In this case a portion of the trapezius muscle was affected. In another case, occurring in a girl of fifteen years, a perfect result was obtained. The postoperative treatment should consist of appropriate exercises continued for about one year.

Dr. William J. Chandler said that, judging from an experience of thirty years, he would say that torticollis

was a rare complaint. He recalled one obstinate case which had developed after measles, and had persisted for a year or two.

Dr. H. S. Houghton said he firmly believed in the existence of the congenital form of torticollis, and recalled the case of a child born with it in which the head was rotated to the left side. After having the child under observation for some time the case had been referred to an orthopedic surgeon, and was now wearing a brace coming up under the chin, in this manner correcting the deformity.

Dr. H. H. Seabrook spoke of eye torticollis, or "head tipping," a condition dependent upon paresis of the eye muscles, generally the superior rectus. He said that Stevens had attributed this condition to the image being focussed on the perpendicular plane. Of course, these cases were not true torticollis, and most of them were transient, the head being tipped only when the patient stopped to look at something. He had seen 365 such cases in the past three years, and thought orthopedic surgeons would do well to bear this in mind.

Dr. Hubbard, in closing the discussion said that when an early diagnosis was made operation was not necessary, other means proving sufficient for correction. The cases referred to by Dr. Seabrook were not examples of true torticollis, for at times the patient was able to hold the head straight, and they were usually relieved by appropriate treatment of the eyes. In true torticollis a downward position of the eyes persisted even after the deformity had been corrected.

**Do Our Present Modes of Living Tend to the Increase of Certain Forms of Nervous and Mental Disorders?**—Dr. C. E. Atwood, of White Plains, N. Y., read a paper with this title. That some forms of insanity were on the increase, the author said, he had first proved to his own satisfaction while preparing a paper on "The Teaching of Recent Investigation Into the Causation of Insanity," read before the Social Science Association in 1891. There was also no doubt that neurasthenia and some allied neuroses were also increasing, and the fact of this increase in nervous and mental disorders he attributed to our present methods of living. By this was meant our rapid and overstrenuous life, its varied and increasing demands upon us and the associated irregularities in eating, drinking and sleeping with a tendency to overindulgence. At first glance many might be disposed to take a pessimistic view of the effects of the present strenuous life, but a closer study of the facts would show that harm was only likely to result when the balance was not maintained by sufficient variety, rest and sleep. Whenever wear and tear were excessive and rest and repair deficient the result was bound to be disastrous, if not in the present, certainly in the next generation. All cellular activity required cellular rest. A nerve cell which had been subjected to five hours of artificial stimulation had been found to require twenty-four hours' rest in order to fully recover from the exhaustion and the changes induced by such activity. What took place in the cell when artificially stimulated probably occurred, to a less degree, in the mental and physical activities of daily life. The normal symptom of cell exhaustion, fatigue, was dissipated by rest and sleep, during which the blood current carried off most of the products and restored cellular activity. This brought up the question of auto-infection. The usual form of auto-infection was that produced by morbid alimentary action. There was, however, a more dangerous form, caused by incomplete oxidation of the products of the worn-out body cells. These products of suboxidation were called alexins. Anything which interfered with complete oxidation probably caused neurasthenia. The autotoxins would produce toxic effects upon the nerve centers. Some neurologists went so far as to say that all forms of insanity were caused by auto-intoxication, but most of them admitted that some varieties had their origin in tabes dorsalis, syphilis, epilepsy, convulsions in early life, etc. Most forms of insanity were due to neurotic and faulty tendencies and inheritance, either in the parents or grandparents, a fact frequently exemplified in cases of chorea and alcoholism. When one recalled the potential traits of the individual, and how each began in the germ plasm, there was little wonder concerning the profound influence of heredity. If normal products showed this influence, it was but natural that abnormal ones should bear evidence of it to a still greater degree. The speaker then referred to the increased per capita use of alcohol in the United States. He said that we were the most nervous people in the world, and that this was probably the result of our mode of life. Overwork did not cause neurasthenia unless it was accompanied by loss of sleep, drug addiction, excessive eating and drinking, etc., thus leading to arteriosclerosis and apoplexy. In 1892 the average age for the occurrence of apoplexy was 58.9 years; in 1902 it was 64.2 years. The brachiocephalic type was found in the cities, the dolococephalic type prevailing there. Mental derangements were increasing among negroes. In 1890 50 per cent. of the insane were of foreign-born parents and 30 per cent. were themselves foreign-born, the Russian Jews vastly predominating.

The number of cases of hysteria and neurasthenia had doubled. Alcoholic neuritis was three times more prevalent, and there was a slight increase in tabes and general paresis. The increasing dangers of our modern life could be offset by teaching hygiene and by change of occupation and securing needed rest. In the opinion of the speaker the "yellow journals" were responsible for a certain amount of crime and suicide. He suggested that the restriction of immigration in certain cases would result in a decrease of insanity.

Dr. Charles E. Quimby agreed with the author as to the probability that apoplexy was caused by a toxemia. The arterial change was not due to high tension but to cardiac, renal and arterial changes throughout the body, though more particularly in the brain.

Dr. Russell Bellamy thought the increased number of neurasthenics was attributable to sexual excesses and lack of segregation in the control of gonorrhea and syphilis; also to the sexes being thrown so closely together, for never before in history had men and women been brought into such close association. In olden times men worked in the field and the women stayed at home; now they worked side by side.

Dr. J. W. S. Gouley said that if he had understood Dr. Atwood correctly the statistics quoted regarding the use of alcohol applied to alcoholic beverages. He felt sure that a comparison of the statistics regarding the per capita use of such beverages in England, France, Germany and the United States would show that we were a very sober nation.

Dr. Seabrook said that the conclusions drawn from the State hospitals would be overthrown if compared with the statistics from private practice, for the foreign element predominated in public institutions. He pointed out that the Chinese and Japanese were a very nervous and dissipated people.

Dr. Atwood, in closing the discussion, said that he had not intended to be pessimistic on the question of alcohol. He then read a portion of an article reproduced from a papyrus six thousand years old, taken from a tomb of the fifth dynasty, in which the author deplored the deterioration of his age, and mourned the good times that had passed away.

## ORIGINAL ARTICLES.

### PRESIDENTIAL ADDRESS ON THE CARE OF EPILEPTICS.

BY FREDERICK PETERSON, M.D.,

OF NEW YORK;

PRESIDENT OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS.

LET me first express my thanks to you for the great honor you have conferred upon me by electing me President of this useful organization. One of the duties of the office is that of opening the annual convention with a brief address.

Interest in the epileptic has grown of late years with a sort of geometrical progression. It now seems scarcely possible that fifteen years ago one could have written that epileptics were the most neglected of all the world's unfortunates; that physicians took no interest in a disease so familiar that little improvement has been made on the clinical description given by Hippocrates 2,400 years ago, so widespread that one person in 500 is afflicted with it, making a total of perhaps 140,000 cases in the United States alone. No general hospital received the epileptic. No school would accept him as a pupil. Playmates shunned him. The church was closed to him. No employer would keep him in his employment after his once having had an attack while at his work. Every avenue for mental or moral development, through occupation, schooling, recreation, and association with his fellows was closed to him. He was a burden to his family. The physician pronounced him incurable, and gave him bromides ad libitum, which while often reducing the number of attacks as often wrought physical and mental deterioration. What wonder then that he grew up dull and ignorant, intellectually feeble, morally depraved, irritable in temper, with tendencies to imbecility and insanity rather than to mental advancement.

There were at that time two refuges open to him, the insane asylum and the almshouse, and a considerable percentage of the population of such institutions was made up of sufferers from epilepsy.

But after twenty-four centuries of familiarity with the disease there was in 1887 a sudden general awakening to the actual state of the epileptic as described above. Simultaneously in England and the United States, movements were set on foot to better his condition. Some years before this a Lutheran pastor in Germany had in a quiet way, and quite unknown to the rest of the world studied the condition of this class, and worked out a successful solution of the whole problem of their care in the noble colony scheme which he inaugurated at Bielefeld. It was the published descriptions of this colony in various English and American periodicals that first aroused public attention in these countries.

It is true that one or two private institutions in Europe had provided homes for epileptics previous to the undertaking at Bielefeld, and it is also true that the State Board of Charities of Ohio had considered long previously to 1887 the need of some special provision for epileptics; but whatever had been done or considered was as nothing compared with the scheme ideally conceived, and successfully executed by Pastor von Bodelschwingh at the little German town in Westphalia. Here grew up from small beginnings a village inhabited solely by epileptics, and their caretakers, instructors and physicians. Here everything was provided to meet their peculiar needs, to make up for their deprivations in the outside world. They were supplied with schools to improve their minds, industrial teachers to make them more or less self-supporting, and physicians to study their cases and improve or cure them. Outdoor occupations were especially favored as helping to ward off attacks. Special diet so useful in epilepsy, was provided. Recreations, amusements and religious instruction were features in the plan. For such as were incapable of improvement or cure, the colony was to be a home, and a home in the real sense of the word; not a great barrack-like structure in which patients might go by numbers, and in droves with lost individualities, but a village of small houses, each of which under the care of housefather or housemother became a little family home by itself. And the spirit which governed this great aggregation of unfortunates, and which penetrated into every home and informed the whole was a unique and wonderful benevolence.

When the success of this scheme became known to the world, its effect in various countries was magical. Immediately steps began to be taken everywhere to provide for epileptics. Other colonies were founded in Germany, in Switzerland, in Holland, in France, and in England. Ohio established the first institution for epileptics in the United States, though, unfortunately, on the hospital rather than the colony scheme. New York has the Craig Colony, at Sonyea, closely modeled on the Bielefeld plan, and with a population today of 825 epileptics, the exact number of colonists at Bielefeld when I first visited it in 1887. Under Dr. Bullard, Massachusetts erected a colony at Palmer. Dr. Sinkler was the prime mover in the establishment of a colony farm at Oakbourne for epileptics in Pennsylvania. There is a New Jersey State Village for Epileptics at Skillman, described by Dr. Weeks in the published report of the Association. A colony for epileptics is in course of construction at Abilene for the State of Texas, an account of which has been

written by Dr. Worsham for the Annual Report of this Association. Dr. Drewry is rapidly pushing the matter of special provision for epileptics in Virginia. There are strong movements on foot for similar projects in Illinois, Connecticut, Indiana, Kansas, North Carolina, Missouri and Minnesota. Dr. Osborne has been indefatigable for years in his efforts to achieve the same purpose in California.

In other countries there has been equal activity. England was the first to found a National Society for the Employment of Epileptics, and a fine colony has been established by this body at Chalfont St. Peter. In addition to this there is one near Liverpool (the Maghull Home), one at Godalming (Meath Home), a large colony at Chelford, just being constructed through the munificent bequest of David Lewis, and finally a fifth institution in England is about completed, for the City of London, not far from Croydon.

A reference to the recently published Annual Report of our own National Association for the Study of Epilepsy and the Care and Treatment of Epileptics (founded in 1898) shows how widespread is the movement for the special care of epileptics all over the world, for here are articles by agitators of the subject in Brazil, Belgium, Switzerland, Sweden, Russia, Italy, Turkey, India, Japan and Australia. At this present session just opening to-day, we shall doubtless hear still further good news of the growing interest in the objects of our solicitude in all quarters of the earth.

The particular purposes of this Association as set forth at the time of its foundation were as follows:

1. To promote the general welfare of sufferers from epilepsy.

2. To stimulate the study of the causes and the methods of cure of this disease.

3. To advocate the care of epileptics in institutions where they may (*a*) receive a common school education; (*b*) acquire trades; (*c*) be treated by the best medical skill for their malady.

4. To assist the various States in America in making proper provision for epileptics.

To these ends we have invited citizens of all parts of the United States to become members and to take part in our deliberations, not only physicians and scientists who may aid us in the study of the causes and methods of cure of epilepsy, but also State officials, jurists, clergymen, teachers, philanthropists, and in fact all persons who for any reason might feel an interest in the objects of this organization. There is no initiation fee, and there are no dues. The association has relied upon voluntary subscriptions for means to defray its expenses. The cost of publication of last year's proceedings, amounting to over $600, was defrayed by Mr. Letchworth, our first president, and the means for issuing the records of to-day's session are already forthcoming.

While we have every reason for congratulation on the amazing accomplishments of fifteen years, there are still directions in which this body can be of service. There are many States of the Union still unaware of the conditions of these unfortunates gathered together in their almshouses and asylums. If in such commonwealths the Presidents of the State Medical Societies would appoint committees of medical men to inquire into the numbers and needs of their epileptics, an excellent beginning would be made, and by arousing general public interest great ultimate good would result. Incidentally, by such schemes already undertaken in certain States, and through the dissemination of literature by this and kindred societies and their members, a new interest in the disease itself has grown up among medical men the world over. More attention is being given to the patients suffering from epilepsy. New remedies are being brought forward. In the laboratories the pathology is being reinvestigated according to new methods. This disorder which has been the *opprobrium medicum* for 24 centuries will surely some day give up to us the secrets of its prevention, causes and cure.

Now, in closing, let me say one word more by way of appeal to those who cannot contribute to the advance of our work in any other way—money could not be better expended than by donations for the following purposes, viz.:

To spread throughout the Union literature relating to the colonization of epileptics.

To establish in the colonies now existing, trades schools, churches, libraries, and other features for promotion of the general welfare of the patients already gathered together.

Last, but not least, to found and endow laboratories in connection with every institution for epileptics wherein the disease may be investigated by trained scientists for the purpose of discovering its causes and its remedies.

---

## NATURE, FREQUENCY AND POSSIBLE SIGNIFICANCE OF THE VARIOUS FORMS OF EPILEPTIC AURA.*

BY WILLIAM P. SPRATLING, M.D.,

OF SONYEA, N. Y.;

MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS; MEMBER NEW YORK ACADEMY OF MEDICINE; AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION; BUFFALO ACADEMY OF MEDICINE; ROCHESTER PATHOLOGICAL SOCIETY.

In its literal meaning the word aura signifies "vapor or emanation from the body, surrounding it like an atmosphere;" though in the sense in which it is employed to indicate a warning of an approaching attack, it has come through usage to have a much broader application. It appears originally to have been used by the ancient Greeks, who thought the fit began in the form of a "spirituous vapor" in the veins of the extremities that ascended to the head, when the patient became unconscious.

For a long time it was held that the nervous impulse or irritation causing the spasm began in the part where the aura first occurred, though now it is generally held that in the vast majority

* Read before the New York Academy of Medicine, Section on General Medicine, April 21, 1903.

of cases the impulse begins in the central nervous system, the sensation only being referred to the periphery. At the same time, there may be an occasional case in which the impulse starts at the periphery, as has been shown by the cessation of the attacks when the local irritation was removed; an irritation like an adherent prepuce, or a stricture of the urethra; or again when the tying of a cord tightly about the member affected would check the progress of the fit. But in all such cases the question arises as to whether we ought to designate them as epileptic, or simply as reflex, or epileptiform.

It is well known how disease of the brain may cause descending degeneration of the spinal cord, or ascending disease in the spinal cord produce disease of the brain. Experiments have proved that a nervous injury in the periphery may not only cause changes in the central nervous system, but structural alterations in nervous tissue and functions in other parts of the periphery.

Brown-Sequard showed this to be true when he cut the sciatic nerve in the leg of a guinea pig and caused structural alteration in the skin of the face, afterward producing epileptiform convulsions by irritating certain portions of the face, then removing the basis of the attacks by excising this epileptogenous area.

We may also mention in this connection the referred sensations in coxalgia, the pain being most sharply felt in the knee and ankle joint, and the acute gastric pains that often follow vertebral disease.

On the other hand, there has been a growing tendency for some years past to regard the aura as essentially constituting a part of the epileptic attack, and this seems to us to be entirely reasonable; fully as much so as it is to regard fever and congestion as preliminary parts of pneumonia, when pneumonia follows. Sometimes the aura arises and persists for an indefinite period and disappears without an attack following; just as there may be fever and congestion of the lungs without pneumonia following. It is, therefore, in our opinion, a good plan to look upon the aura as the commencement of the fit, not simply as a warning of its approach, and to treat the case accordingly.

Unfortunately this cannot often be done, for it is rare for the physician to see the patient before the convulsion has occurred, the aura being not far removed from the attack itself, generally not more than a few seconds, occasionally half an hour or so, while in very exceptional instances the period is longer.

We can best study the various auras by grouping them under four heads as follows: (1) psychic, (2) sensory, (3) motor, and (4) irregular. The first including some disturbance in the patient's mentality; the second some disturbance in sensation; the third some disturbance in his motor system; while the fourth embraces elements of two or more, or even of all of these.

It is difficult to say which of these forms of aura possesses the greater clinical importance, though because they so greatly outnumber all the rest we incline to attach the greatest weight to those of a sensory nature; those in which a feeling of some kind, a numbness, or tingling, or pain, or feeling of discomfort, is felt for variable and indefinite periods before the fit comes on.

In a close analysis of 815 males and 510 females for the establishment of individual auras, it was found that 319 males, equal to 36⅓ per cent. of the entire number, and 186 females, equal to 36½ per cent. of the entire number, had a sensory aura of some kind. It is worth noting how remarkably even this form of aura ran parallel in the two sexes.

In the same cases, 33 males and 19 females had psychic auras, the 52 cases in both sexes constituting less than four per cent. of the entire number, while 22 males and 10 females, 32 in all, a fraction over two per cent. of the total, had a motor aura of some kind. Combining all who had an aura of some kind, we have a total of 589 out of 1,325, equal to about 45 per cent., leaving 55 per cent. who had no aura.

It appears from this that less than one-half of all cases have a specialized aura, though it is best not to regard this as conclusive, for it is reasonable to suppose that some epileptics of low intelligence experience sensory auras they are unable to describe. Allowing for these, it seems safe to say that 50 epileptics out of every 100 have an aura of some kind.

This proportion is much greater than that mentioned by Echevveria, who states that a perceived aura was found in 10 per cent. of the males and 11½ per cent. of the females in the 306 cases studied by him.

Gowers classifies the auras under seven groups, in substance as follows: "(*a*) unilateral; (*b*) certain general auras such as sensations in the limbs, tremors, faintness, etc.; (*c*) auras referred to certain organs, especially those supplied by the pneumogastric nerve, most of the visceral warning coming under this head; (*d*) vertigo and allied sensations; (*e*) certain sensations in the head, pain, etc.; (*f*) psychical auras, the consciousness of an emotion or idea; (*g*) special sense warnings, some of these being unilateral;" and in 1,000 cases found

(*a*) A unilateral aura in 86, topographically distributed as follows: in the arm in 45 cases, legs 15, face 17, tongue 7, trunk 2. (*b*) Bilateral general aura in 74, in the arms 11, legs 12; shivering, trembling, nausea and weakness in 51. (*c*) Auras affecting organs, 106. (*d*) Fainting and dizzy aura, 90. (*e*) Head aura, 50. (*f*) Psychic aura, 25. (*g*) Aura of the special senses, 119.

A total of 600 epileptics out of 1,000 cases observed by Gowers had an aura of some kind.

According to Binswanger, Herpin found an aura of the sense organs in 27 per cent. of all cases; while Bennett found an aura of some kind in 34.4 per cent., the latter finding the aura relatively rare in major epilepsy and far more frequent in the milder forms, a fact verified by our own experience.

Voison* and Féré† classify the auras under four heads: motor, sensory, sensorial, and intellectual, following that used by Dela-Siauve, but neither give an estimate of the proportion of each, Fere stating that "it (the aura) is very frequent: O'Connor has found it in 78 cases out of 100."

According to Féré, "Thorion claims that the epileptic crisis is preceded by a greatly increased elimination of the urinary elements, a veritable discharge; this chemical aura he thinks might even enable one to predict the return of the attack."

It is impossible to estimate with accuracy the number who have irregular forms of auras, but they are not common, occurring less frequently than those of a psychic nature.

This form was illustrated in a woman who first experienced a feeling of buoyancy and exhilaration, that later on gave way to a highly emotional state that persisted for several days, and sometimes even for weeks, before an attack; while for two or three days before the attacks a motor aura in the way of uncertainty of gait, the patient stumbling along as though half tipsy, or the inability to grasp or pick up a small object like a button or a large needle, appeared and grew more pronounced until the fit was over, when this bilateral paretic condition and unbalanced emotional state both completely disappeared.

Psychical aura may appear in the form of a sudden abnormal mental state, leaving a definite impression on the memory, due to the fact that brain processes which attend mental states may leave a residual effect which makes it possible for their subsequent revival, the perception of which we are apt to refer to as "psychical sensations."

The most common form assumed by the psychical aura is the sudden acceleration of the imagination, a quick overflowing of the processes of thought, in which the train of the imagination, ever rapid, is rushed ahead with trembling, excited haste, until the thread is snapped and unconsciousness occurs.

In some cases this stimulated speed of the imagination may be preceded by confused ideation, with different memory pictures appearing momentarily in succession.

Romberg mentions a young man with epilepsy who for nine years had the same recurring thought which was never quite clear to him and which caused him great unrest. He endeavored to free himself from the idea which took the same course every time, to disappear with the beginning of the attack.

Binswanger states that "similar observations in which in each attack definite memory pictures appeared in 'glaring psychic illuminations' are found still in the literature."

When such sensations precede an epileptic fit, they may also be in the simpler form of an emotion or an idea, the former generally being in the form of fear, an apprehension of something evil about to occur, the patient being genuinely frightened and attempting to run away. We have seen a number of cases in which the patient's face wore a terrified aspect, in one or two instances trying to run away from danger the patient felt in some way impending. The presence of the feeling of fear is also testified to by patients who involuntarily show fight when interfered with while in a seizure or just as they are going into one.

A young man was subject to frequent attacks of psychic epilepsy, during which he would appear pale, confused and ill for some time before the fit, and not infrequently got into trouble in public places by assaulting the person who felt it his duty to care for him when he seemed to require it. If let alone, he would pass through the seizure all right, but the moment a hand was laid on him to assist him, he became extremely violent and would fight with great vigor until he was overpowered. He was always ignorant of his acts in this respect after his fit was over.

Fear of a primary, instinctive, and therefore of an unreasoning kind, is the type met with in psychical aura, and it springs from the instinct of individual conservation.

According to Th. Ribot, in "The Psychology of the Emotions," fear is the first, in chronological order, of the instincts to appear, showing itself, according to Preyer, at twenty-three days, according to Perez, at two months, and according to Drawin, at four months.

Ribot then goes on to speak of the characteristic marks of fear, so far as it affects the innervation of the voluntary muscles; of the muscles of organic life, and finally of the vaso-motor apparatus, the concrete results making a very distinct picture of the condition of fear.

The very interesting question now arises as to how fear can be artificially induced; in other words, what is the process that brings it into existence so that it stands for a symptom in part of an epileptic convulsion? If we could answer this, we could place at least a part of our psychological studies on firmer ground.

The warnings which take the form of "ideas" are generally dependent on special sense conceptions, especially on vision. Gowers mentions a woman who saw London in ruins, the Thames emptied to receive them, and herself the lonely survivor. This he calls a manifest "psycho-sensory warning."

All special disturbances such as these have the same basic meaning; they indicate some instability of the centers connected with the psychical processes.

We have just referred to a woman who had an irregular aura, the first part of which was psychic and which gave her a feeling of great buoyancy and exhilaration. While this is not a common aura, it is distinct in type and of more than passing interest.

Binswanger in describing the disturbances of

* L'Epilepsie, 1897, p. 54.
† Epilepsy, Twentieth Century Practice of Medicine, Vol. X, p. 593.

feeling due to an approaching attack, states that "more rarely we find sensations of serenity, placidity, calmness, sudden apparitions of joy, rapture, colossal lightness, an elevating good feeling. Some patients declare that in the beginning of the attack they feel freed from a heavy burden." This exactly portrays the emotional state the Russian novelist Dostoieffsky, who suffered from epilepsy, applies to himself in "Besi."* "There are moments," he writes, "and it is only a matter of five or six seconds, when you suddenly feel the pressure of eternal harmony. This phenomena is neither terrestrial nor celestial, but is an indescribable something which man in his mortal body can scarcely endure. . . . The terrible thing is the frightful clearness with which it manifests itself and the rapture with which it fills you. During those few seconds, I live a whole human existence."

Sensory auras are vastly more common than all the rest and partake of the greatest imaginable range in character. They may be confined to the special senses and include perversions of taste, of smell, of sight and of sound. Any abnormality in the functions of the special sense organs may be fleeting and transitory, or may in some instances persist for hours before the fit comes on.

Visual auras greatly predominate, occurring as often as those of taste, hearing and smell combined. They usually take the form of flashes of light; the colors of the rainbow passing in rapid succession across the field of vision. In other instances they appear in the nature of optical illusions; people, dogs, cats, wild animals of various kinds being engrafted on the visual field; while it still more rarely happens that temporary blindness immediately precedes the attack—Amaurosis epileptica. In some instances the sudden loss of sight may alone constitute the entire attack, the area of the discharging lesion being so circumscribed as to produce no other results; many cases of persons being suddenly stricken blind doubtless being due to this simple cause.

The following instances taken from the author's cases are typical of the more common forms of visual aura: "Flashes of light, then blackness;" "an object passes before the eyes five to ten minutes before the attack:" "dark objects move before the eyes;" "blurred vision;" "flashes of blue and red;" "flashes of light of the rainbow colors;" "at times sees colors;" "sees wavelike motions in the air just before the fit;" "at times have loss of vision:" "visual percepts of light:" "vapor before eyes and numbness in paralyzed hand:" "eyes get dim:" "visual aura at times—sees a policeman:" "partial blindness:" "sees black, then a yellow light;" "occasionally a visual aura—sees stars, at other times the aura is epigastric;" "sees some animal approaching:" "everything looks bigger than it ought to be just before the fit; people, chairs and tables are magnified."

According to Sir William R. Gowers, it is not surprising that when central instability exists, the visual center should often lead the way in the sudden derangement of balance, for light constitutes the most rapid form of motion of which we have any perception, consequently it must be associated with a corresponding degree of delicacy in the central stimulus that receives new impulses produced by waves of light.

In addition to the forms of visual aura in which colors predominate, other sensations occasionally affect the eye just before a fit; one of these being diplopia, or double vision, a case of this kind being mentioned by Gowers, in which the diplopia was associated with an aching in one eye and an apparent magnification of objects to twice their usual size.

This curious condition is seldom encountered, the probable explanation of it being found in the increase or diminution in the sensitiveness of the visual center, which produces an effect on consciousness analogous to that produced by the stimulation of a larger or smaller area of the retina by a larger or smaller image.

A male epileptic, twenty-four years of age, that came under my care, had this aura, objects about him increasing greatly in size 10 to 12 seconds before the fit appeared.

In a few cases there is a sensation of pain in the eyeball, due probably to some irritation of the fifth nerve, these cases generally having a motor element in them, such as twitching of the muscles about the eye.

Gowers reports a case* that came to autopsy in which the fits were preceded by a flash of light or pain in the eye, the autopsy revealing the presence of a tumor in the occipital lobe, which extended as far forward as the angular convolution.

In addition to all these, there have been reported cases of highly specialized visual sensations in the form of complex visual conception, or psychovisual auras; that is, a psychical aura, crowding itself in upon the patient's field of consciousness coincident with the appearance of some distorted visual percepts. For instance, a woman first always saw bright lights—red, green, yellow—and then the lights continuing, she saw a girl "and tried to get to her to ask what the lights meant," and then fell in a fit.

When one color only is seen, it is most apt to be red or blue; the most prominent order of appearance of the colors being red, blue, green, yellow, and occasionally purple. This order is not in harmony with the physical relation of colors, nor does it correspond to the areas of retinal perception, for red, which is oftenest seen, has one of the smallest retinal fields. On the other hand, it does correspond to a certain extent with the degree of visibility of colors, for Gowers credits Cohn with having observed that the order in which spots of color one millimeter in size can be seen in direct sunlight at a certain distance, is as follows: red, blue, green, yellow, violet, which appears to be very nearly the order they appear as auras in epilepsy.

Occasionally we find auditory and visual auras associated, though this combination is rare, while

* The Man of Genius, by Lombroso, 1891, p. 339.

* Epilepsy and Other Convulsive Diseases, p. 79.

we have knowledge of one case in which there was complete unilateral loss of hearing just before the fit.

Auditory auras partake, as a rule, of the nature of the following: "Roaring and voices heard two or three minutes before the convulsion appears;" "roaring in the ears;" "sound of sea waves in the ear before mild attacks;" "roaring and buzzing in the ears;" "noises in the head for a brief period before the attack;" "roaring followed by a sensation of falling."

Auditory auras occur about one-fourth as frequently as those of a visual nature, which are generally present in two per cent. to three per cent. of all cases.

In addition to the forms of auditory disturbance enumerated above, the patient may hear sudden sounds of almost any nature, like the crash of a heavy falling body, the blowing of a whistle, the ringing of a bell; while more rarely there may be the sounds of voices or of music alone.

L. Pierce Clark* quotes Sante de Sanctis and A. Christiani as reporting three cases in which the patients indulged in a variety of songs while undergoing mild convulsive movements: two of them keeping time to imaginary music with rhythmic movements of the body, these two showing some clonic muscular movements in the lower extremities, while the third sang a single tune, accompanying it with movements imitating an orchestral direction.

The writer is familiar with the cases of two young adult male epileptics, one of them victim of an infantile palsy affecting the right hand and foot, both of them subject to grand as well as petit mal attacks, the latter form being not infrequently announced in each by a period of involuntary whistling. I had occasion to witness this phenomenon in one of them five times in one day, the first indication of an attack being a sudden cessation of all movement on the part of the patient; he would stop and stand still if walking, followed by a confused, puzzled expression, when he would grunt quite audibly two or three times, and then whistle a bar from a popular song of the day, repeating it with the next convulsion in the most precise manner. He was fully cognizant afterward of what he had done, as shown by the fact that he always turned to me with the question, "Did you notice that one?"

On one of these occasions, he caused a bank cashier with whom he was dealing at the moment, much astonishment and concern by suddenly repeating the usual grunt two or three times, then whistling a bar from a popular opera while arranging an important financial transaction. None of the anomalous states lasted more than five to seven seconds. At times they appeared as epileptic equivalents, at others as forerunners of more pronounced convulsions.

We recall two cases in which mild seizures were accompanied with complete auditory deafness, the patient's sight remaining normal, so that motions made to the patient to do certain things were immediately obeyed, while spoken commands were unnoticed.

Extraordinary sensations in connection with olfaction and the gustatory sense are occasionally met with, while they take the greatest possible range in character and are generally of an unpleasant nature.

Gowers thinks it significant that flavors which are perceived only through the olfactory nerve seem to be associated with taste in the central discharge which causes the warning, the flavor in this instance being of a kind that enters the posterior nares, causing a simultaneous stimulation of the true gustatory nerve.

Some epileptics experience a bitter taste, like quinine, while others have a metallic taste in the mouth that sometimes persists for an hour or more before the convulsion. One patient complained of a feeling of "numbness in the tongue," as though that organ had been completely cocainized, while Watson mentions an epileptic who could abort an approaching attack through voluntarily biting his tongue quite severely, doubtless having first experienced an unusual sensation of some kind in it.

Hughlings-Jackson* speaks of having drawn attention to a group of cases in which there is at the onset of the paroxysms a crude sensation of smell or of taste, in which there are movements of chewing, smacking of the lips, and sometimes spitting, all being ascribed to disturbances in the cortex. Some of these are foreshadowed by an epigastric warning.

A. T. states that he almost always has light attacks following severe ones at night, and following the light attacks he has a peculiar taste and sensation in the mouth which he describes as follows: The first is a "sour taste;" the second similar to that of "wheat bran in the mouth;" the third a feeling of "stringiness," combined with "numbness in the upper part of the mouth;" the fourth a "sickish, sweet taste" great enough to produce extreme nausea; the fifth a "filthy, nasty taste" which is extremely disagreeable; the sixth and last being a feeling of "sliminess" in the mouth.

These disorders of taste may persist for a day and gradually shade out from the sixth condition to that of normal sensation.

The morning following the patient feels "unusually well;" much more so than during any time more distant from his seizures. These disorders of taste persisted for years, and patient states that they cannot be ascribed to stomachic indigestion.

According to Ferrier, the senses of taste and smell are located in the uncinate gyrus, since reflex irritations of this gyrus in the animals he experimented on produced "reflex" movements analagous to those just mentioned as occurring in the human subject prior to, or as a concomitant of lesser epileptic convulsions.

*The epigastric aura* is more commonly met with than all the other sensory auras combined, its presence having been noted in some form in 200

* Medical News, Sept. 1, 1900.

* The Lancet, Jan. 14, 1899.

cases, equal to 15 per cent. of the 1,325 studied by me.

The nature of this aura is not very variable, for it quite constantly appears in one of three forms: the first and most common being that of "a gnawing, indescribable, indefinable sensation at the pit of the stomach" that lasts anywhere from a few seconds up to, but rarely beyond, half an hour before the fit is established; the second being "a deep-seated burning pain;" the third "a feeling of nausea that grows in intensity and rises like a choking sensation toward the head until the sensation reaches the throat, when consciousness is lost;" the latter closely resembling the globus hystericus.

The location and cause of the pain in these cases is entirely problematical. They may be due to some disturbance about the centric origin of the vagus nerve, which has a wider distribution than any other of the cranial nerves, supplying the organs of voice and respiration with both motor and sensory fibers, the pharynx, esophagus, stomach and heart with motor fibers. Its immediate communications are extensive and remote, while the seat of its origin is in control over the two vital processes of respiration and circulation.

The rhythmic sequence of the respiratory movements are apparently due to periodic discharges from the respiratory center located in the floor of the fourth ventricle on each side of the median line, the two halves being intimately connected by commissural fibers. The cause of this periodicity is obscure, but since it has been shown* that after the combined section of the vagi and glossopharyngeal nerves, the spinal cord in the lower cervical region, the posterior roots of the cervical spinal nerves, and the separation of the spinal bulb from the parts above, the rhythm continues, indicates that such periodicity is inherent in the nerve cells and is not caused by external stimuli carried to the center through afferent fibers.

Loewy has shown that under the above circumstances, the rhythm is due to the blood "which, while acting as a continuous excitant, causes discontinuous or periodic discharges," and since the blood supply is under nervous control, the respiratory center is automatic only with reference to external nerve stimulation.

The problem in epilepsy that rests on this point is to determine whether the initial disturbance, *the thing that breaks up the rhythmic periodicity of the respiratory impulse*, is to be sought in the respiratory center primarily, or whether it lies somewhere in the periphery, in the stomach or heart, or especially in the circulation, and is carried by some vital process to the seat of the respiratory life.

It is unusual for the epigastric aura to be referred to any other locality than the immediate region of the stomach. In one case the pain first appeared in the right ileac region, and was always attended with a feeling of nausea, and it is noteworthy that while the vague sensation that nearly always accompanies it passes upward to the throat and head, the pain remains stationary in the region of the stomach. As a rule, as soon as the aura reaches the head, consciousness is immediately lost.

Many cases that exhibit the epigastric aura suffer from indigestion, that makes its appearance to some extent periodically; other stomach disorders being distention, gastric catarrh and flatulence.

It seems now a problem as to whether these conditions precede or follow the initial manifestations of the fit, and on this point we differ with Sir William R. Gowers, who goes so far as to say, "We are not justified in assuming that flatulence is the cause of the attack any more than we are in regarding gastric disturbance as the cause of an attack of migraine which subsides with vomiting." It seems entirely rational to hold that while the flatulence itself may not induce the attack, the conditions that caused the flatulence may alone be to blame for it; for the reason that correction of deep-seated disturbances in the processes of nutrition often possess the power of lessening or entirely removing the cause of the attacks.

All this leads to a belief in the importance of studying chemical pathology as a cause of epilepsy, a vast, prolific field as yet but little explored and still less understood. At the same time, we do not wish to be understood as claiming that the cause in such cases is never wholly centric, for minute, capillary hemorrhages, or small spots of softening due to thrombus or embolism or other lesions we are not yet familiar with, may act in the same way.

It is often difficult to determine *motorial* forms of auras from the beginning of the convulsive period itself. Indeed, as we have previously stated, auras of all kinds might very properly be looked upon as the entering wedge of the fit itself, notwithstanding that it may at times come and go without expanding into a convulsion.

We recall the case of a man, twenty-eight years of age, who had a persistent motor aura in a jerking movement that began in the right arm, just enough at first to lift the arm a few inches from his lap, but that grew stronger each time, the jerks being two to three seconds apart, until the arm was raised at each impulse straight above the head. So soon as this condition was reached, the jerking would commence in the left arm, and after it had gone through the same course, so that both arms were finally being jerked over the head at each impulse, a general convulsion would appear, the whole body being involved, the patient dropping unconscious to the floor. It required at times half to three-quarters of an hour for these motor manifestations to develop up to the convulsive point, a sufficient length of time to administer a remedy that often served to abort the attack.

One of the most common forms of motor disturbance is that of running just before the fit, the so-called Procursive Epilepsy. Cases that exhibit

* Vide American Text-book of Physiology, p. 458.

this phenomenon are rare, and as a rule are apt to be extremely violent during the attack. We recall the case of a boy who would start and literally run like a deer for half a mile before falling in an active convulsion, which was always followed by great exhaustion.

Another case of the kind was that of a young married woman, who seemed to possess superhuman strength from the way she demolished the stoutest woodwork when in a grand mal seizure, and who could not be allowed out of the hospital for a walk because when about to have an attack, she would run far enough away from the attendant to get lost.

When a seizure appeared while she was on the ward she would run at breakneck speed its entire length, about 120 feet, jump up and thrust both legs through the window and out through the spaces between the iron bars, remaining in this position until the worst of the convulsion was over, it being almost impossible to tear her grip loose from the iron bars.

Gould and Pyle (Anomalies and Curiosities of Medicine, p. 852) mention "a peculiar case of epilepsy, the patient being a workman who would be suddenly seized with a paroxysm and unconsciously run some distance at full speed. On one occasion he ran from Peterboro to Whittlessy, when he was stopped and brought back, while on another occasion he ran into a pit containing six feet of water, from which he was rescued."

Echeverria* described the case of a woman, twenty-two years old, who had general convulsions that always occurred in the day time, the attacks being preceded by an uncontrollable desire to run. If held at the time and violently shaken, the paroxysms would occasionally be cut short and their intensity diminished.

These "running fits" came on at the age of twelve years and grew steadily worse, until the girl's mind was practically destroyed. As a remedy, it was directed that "she try violent exercise at skipping the rope in addition to having a seton in the back of her neck, and being made to take large doses of the bromide of potassium and conium:" the author adding, "The perturbation caused by the violent jumping evidently proved of great avail. No fits repeated in the course of three weeks after commencing the above treatment joined to a tonic regimen."

The same writer mentions that violent exercise in a trapeze controlled the spasms in another patient; the patient resorting to the practice of his own accord in the belief that bodily fatigue would keep off the convulsions.

A carpenter's son, a young man of twenty-four years, of powerful physique, often showed the first evidence of an attack by suddenly springing into the air, sometimes with such force as to turn a complete somersault, generally falling on his back and head; immediately after which clonic contractions would set in, those being so violent as to require five to six strong men to hold him so that he would not injure himself too severely; but as it was, his body for weeks after an attack was often covered with sores, bruises and scars.

Other epileptics turn completely around one or more times before the attack comes on, the direction of turning being uniform; that is, if they turn to the left this time, they will turn to the left in subsequent attacks. Some walk backward a few steps, then fall heavily, striking on the occiput, repeating this often enough to keep an unhealing wound on the scalp at that point, unless a pad is worn to prevent it.

"Trembling from head to foot," as patients describe it, is witnessed in some cases, conjointly or not with an epigastric aura, while a feeling of "giddiness" just before the fit is comparatively common.

Isolated contractions of certain parts of the body, like the thumb or fingers, or the great toe, may also announce the coming of an attack.

A woman who came under the writer's care a few years ago, began at one o'clock in the night to have a series of convulsions that were checked after the eighth one, to recur six hours later, and that kept recurring 49½ hours, when 549 had taken place, the initial spasm each time being the sharp, clear contraction of the first phalanx of the right thumb. After the two hundredth seizure, the patient went into status, the temperature gradually rising to 107° F.; death occurring just at the beginning of the third day.

Some have a warning of an attack in "a sleepy feeling," somnolence. It is impossible for them to keep normally awake. This feeling may exist for a day or so before the convulsion appears, being exactly opposite to another state in which the patient feels "unusually bright and active, mentally and physically," for some time before the fit, to be plunged into painful dejection after it is over.

H. N. Moyer* reports the case of a young man of good family history, and correct personal habits until the age of fifteen years, when he became an alcoholic. At nineteen he was nervous, and had hallucinations during his waking hours—seeing strangely formed animals approach him several times. In 1895 he became afflicted with a tendency to sleep, so that he had frequently to lie down several times a day for the purpose—20 to 50—the patient himself states, sleeping only a few moments each time.

While running an elevator he would sleep while passing several floors. He had other attacks which he described and which differed from the ordinary sleeping attacks. "Once at the table he suddenly became unconscious, the attack probably being epileptic."

It is difficult to say to what extent, if at all, these attacks of somnolence may have preceded the lighter forms of psychical epileptic convulsions, but it seems probable that toward the last, at any rate, they must have been most intimately associated with the epileptic state. Complete obscurity at present surrounds the cause of these conditions. Clinically, the first appears to re-

* Epilepsy, p. 257.

* Medical Record, Nov. 19, 1899.

semble somewhat the so-called sleeping sickness that has been prevalent of late years in certain portions of Central Africa, and which investigators of the London School of Tropical Medicine seem to think is due to a low form of chronic meningitis. In this disease death invariably follows, which is not the case in the somnolent forms of epilepsy, *i.e.*, somnolent through the prodromal period only; the patient being as bright and as well as ever after the effects of the convulsion are over.

In rare instances the heart is the seat of disturbance that indicates an approaching attack, some pain, but more particularly a "feeling of distress" being felt in the cardiac region, palpitation being comparatively common.

When cephalic sensations are experienced, they are generally dependent upon the extension of an aura that had its origin in some other part of the body, like the stomach, though there is occasionally a sense of "fulness," or "a rushing sensation," experienced in the head or throat, altogether independent of any disturbance anywhere else.

In conclusion, my experience leads me to believe that the more sudden, severe and complete the epileptic attack, the less likely it is to be preceded by an aura, while the further the convulsion departs from the classical type, the more common and distinct the aura; and while at present we make but little use of these important initial manifestations of the epileptic state, they justify close and analytic study as contributing possible guides to the seat of the disease.

## THE DAILY RHYTHM OF EPILEPSY AND ITS INTERPRETATION.

BY L. PIERCE CLARK, M.D.,

OF NEW YORK;

CLINICAL ASSISTANT IN NEUROLOGICAL DEPARTMENT VANDERBILT CLINIC; FORMERLY FIRST ASSISTANT PHYSICIAN AT CRAIG COLONY FOR EPILEPTICS, AT SONYEA, N. Y.

THAT all force has a tendency to assume a rhythm is a fundamental postulate of physics (Spencer). Disease rhythm or periodic variations in the symptoms of general disorders has been an important factor in diagnosis and prognosis for many years. Some sort of rhythm attends all nervous processes both normal and morbid. This is a fact well proven by biological and psychological experimentation. Disease rhythm (not of muscle movements) in the chronic convulsive disorders is perhaps the most noticeable. This is particularly in evidence in the single or multiple tics, choreas, myoclonies and paralysis agitans. Their rhythmic variation are usually designated "good" and "bad" days. All forms of the insanities have well-recognized clinical stages of remission and exacerbation. As the pathology in the convulsive affections approaches nearly an organic basis in which parenchymatous and interstitial changes play the chief rôle, we must seek their principle of pathogenesis in an initial toxin or autointoxication. The rhythm of the pathogenesis must also be present and consequently fresh opportunities should be at hand for physiological chemists to grapple anew the many serum problems connected therewith.

The tempting field of wider amplitude of rhythm in the epilepsies as shown in the seasonal, menstrual in women and general meteorological variations, will not be considered here, but remarks will be limited to an exposition of the daily rhythm and its interpretations.

In 1897 (*Medical Record*, April 17) I collected and tabulated 9,545 epileptic seizures by hours for the purpose of determining the existence or not of a definite curve. In the compilation the early morning hour, four o'clock, appeared the greatest hour of frequency. The study quite contradicted the conclusions of Féré in a collection of 1,938 seizures from which he inferred that the eleventh hour was the period of least frequency; in mine, the hour before noon was the sixth in order of frequency. For this and other obvious reasons I determined to review all the data procurable and study the subject at great length. During the next four years I carefully collected data from epileptics of both sexes in three different groups comprising those of varying types of the disease who lived under dissimilar conditions and who were engaged in different pursuits. All the cases from which data was collected were under my immediate care and attention at the Craig Colony for Epileptics, at Sonyea, Livingston Co., N. Y. The sum total of the study comprises 150,000 epileptic seizures. The general manner of life at Sonyea has been excellently detailed by Drs. Peterson and Spratling at various times and need not be dwelt upon at length here. Suffice it to say that it is a country life adapted to the semi-invalidism of the epileptic class under hygienic regulations and control as regards occupation, diet, baths and medical treatment. Lest sedation might be considered as a hindering factor in the study with its well-known tendency to modify the rhythm in individual cases, I may say that the bromide treatment was at the minimum during a large part of the study, and in group three it was practically nil throughout the entire collecting period.

TABLE I.

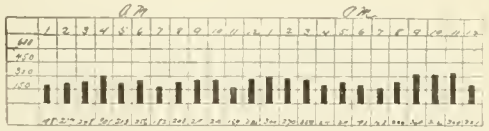

TABLE I.—An hourly analysis of 5,677 attacks occurring in about 25 epileptic men and women for a period of 18 months in the Peterson Hospital. Severe type of epilepsy.

Table I includes all attacks which occurred in the Colony Hospital for a period of eighteen months. A total of 5,677 seizures in an average number of 25 patients equally divided between two sexes. Serial and status periods are comprised herein, and it can be positively stated that every seizure of the twenty-four hours was cer-

tain of record, a fact of no mean importance and often overlooked in the heterogeneous collection of such data from private and unreliable sources. The character of the cases in the hospital was representative of the colony at large. All forms of epilepsy were shown. The character of the diet and hours of meals (7 o'clock A.M.; 12 noon; and 6 P.M.) varied but little from the institution proper, and consisted of light breakfast of cereals with weak coffee and bread and butter; dinner of soup, meat, vegetables and plain pudding; supper of bread and butter, stewed fruit, milk or weak tea.

The great majority of the patients were bed cases and the hours of sleep were from 8 P.M. to 6:30 A.M. The life for those not in bed was largely sedentary and unemployed; a few indulged in open air exercise. The data of this record would have been quite ideal for statistical study if no more serial or status periods were embraced in it than that chargeable proportionately to 25 patients, but every severe case of serial epilepsy and status epilepticus occurring at the colony is sent to the hospital for treatment. However, this data may form a legitimate part of the whole picture. In considering curves or maxima periods of frequency, we find three fairly distinct exacerbations ranging themselves: that of the early night or 9 P.M.; that of 4 A.M. or early morning; that of noon or 12 P.M. A tendency to the formation of smaller or secondary curves at 9 A.M. and 4 or 5 P.M. may here be noticed also.

TABLE 2.

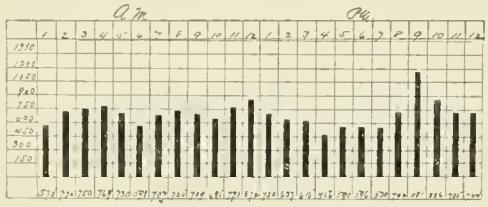

TABLE II.—An hourly analysis of 16,762 attacks occurring in about 40 epileptic men and women for a period of 3 years in mild type of epilepsy; the Letchworth House.

Table II is composed of 16,762 attacks occurring in about 40 men and women, equally divided, for a period of three years. The grade of cases were from the middle class of epileptics. The men were largely out-of-door workers on the Colony farm, and were of about the grade of those usually so employed at farm labor. The maxima periods appear similar to that in Table I, at early evening or 9 o'clock P.M., at noon, and early morning or 4 o'clock A.M. The more marked tendency to the formation of secondary curves in the early morning at 8 or 9 A.M. and in the late afternoon at 4 or 5 o'clock P.M. is also quite apparent in this chart.

Table III is made up of 18,494 attacks occurring in the idiotic, imbecile and demented male epileptics. They have no occupation and the life

TABLE 3.

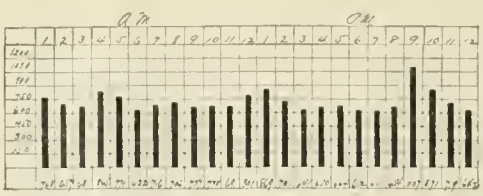

TABLE III.—An hourly analysis of 18,494 attacks occurring in 70 feeble-minded and demented epileptic men for a period of 18 months; West House Group. Severe type of epilepsy.

is a sedentary one. The maxima are similar to the preceding tables.

Table IV is a grand total of the different groups here given with a further accession of 110,067 seizures collected impartially from all the groups, thus making a sum total of 150,000 seizures.

A chart of about 40,000 seizures compiled from the women's group exclusively, was discarded as its accuracy was seriously in question. It was, therefore, not used as data in the sum total. I have no reason to doubt but that if it had been carefully compiled it would have presented the same general characteristics as that of those already given.

In Table IV the same general curve or maxima periods are present as in the preceding component tables. The hours or period of greatest frequency is that of the early evening or 9 P.M., and secondly, that of 12 o'clock noon to 2 P.M., and thirdly, that of 4 to 6 o'clock in the early morning. It is much less misleading to speak of the maxima as grouping themselves at a particular period rather than at a particular hour. If this be done we shall find that all the tables practically agree. The secondary curves become still more prominent in this last chart. The attacks are

TABLE 4.

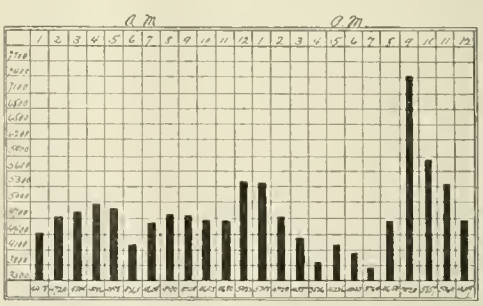

TABLE IV.—An hourly analysis of 150,000 epileptic seizures comprising the three preceding tables with the addition of 110,067 from all three groups.

quite evenly divided between day and night. It may, therefore, be stated that there does exist well-marked and fairly definite periods or rhythm in epilepsy. It is divided approximately into eight-hour periods with tendencies to the formation of secondary rhythm about midway between.

The maxima periods in their order of frequency are in the early part of the night, in the middle of the day and in the early morning.

I submit in explanation of the daily rhythm in epilepsy that we must consider in the first place the auto-intoxication, just as we regard the predisposition to epilepsy in general so must the auto-intoxication be reckoned with in the interpretation of the daily variation; in the second place, as the exciting agent or rather as a permitting factor of a negative sort, stands the lowered inhibitory control supposed to be a general function of the cerebral cortex in its totality.*

The lessened inhibitory control is expressed particularly in the degree of depth of sleep. In point of fact the seizure curve at night may be taken as an inverted curve for blood-pressure, depth of sleep and cerebral inhibition. Probably the diminished blood-pressure and the cerebral anemia supposed to occur in deep sleep are coincident and contributing factors to the sleep state.

Sleep, which is the diastolic phase of cerebral activity, is deepest in normal individuals the first hour or one and three-quarters hours (Minninghoff and Preisbergen) after retiring; it deepens at first quickly, then more slowly; it then lightens and remains indefinitely light; an hour before waking it is very light, nearly as light as the first part of the night. There is a final deepening but of course not so marked as that seen in the first sleep at retiring. Sleeping deeply implies literally sleeping down through all the level or neuron orders. In deepest sleep I have never been able to obtain knee-jerks and plantar responses except by such severe stimuli as to awaken the patient. In the reverse process of awaking the lower reflexes are released first and may on stimulation be made to overact. This is in brief an epitome of our present knowledge of the sleep state and the reflexes.

Physiological and morbid crises occur frequently in the light sleep periods such as nightmare, night terrors, nocturnal emissions, somnambulism and epileptic seizures. The fact that the individual passes into deep sleep rapidly on first retiring discourages the occurrence of the crises just mentioned, nevertheless I found in extended observation upon certain cases where deep sleep does not quickly occur and where it remains indefinitely light in the early retiring period that epileptic crises of varying degree of severity and frequency occur. The return to light sleep after the first period of deep sleep is comparatively speaking gradual and consequently permits the occurrence of the highly organized cerebral reflex process of epileptic seizures. However light the sleep the cerebrum which is the seat of the general function of inhibition is in abeyance and in result permits all reflexes (literally not asleep) to run riot. This theory explains also the early morning frequency.

It must be distinctly understood that the negative state of cerebral inhibition in the light sleep periods does not cause anything, much less the occurrence of epileptic seizures, but permits their occurrence by letting go of the normally inhibited lower reflexes. Epileptic seizures are a sensory-motor reflex, comparatively high grade in character as they are functions of the cerebrum itself. The auto-intoxication must be the active agent in its excitation. I cannot but believe that the modifications in the condition of blood-pressure cardiac and respiratory activity, body temperature and secretory variations are but coincident factors to the sleep state and dependent upon it rather than the reverse. They all may and probably do contribute their share in the general occurrence of the climax of auto-intoxication.

The explanation to the noon frequency is more difficult than the night rhythm, as in the latter case the external conditions are largely at a minimum. However the noon frequency may be explained as follows: The patient is fatigued and inactive for the first time since awakening. This inactive period may properly be termed day sleep; it is a time of day dreams and is quite comparable to the light sleep during the night. Then, too, this period, 12 to 2 o'clock P.M., is the time of ingestion of the heaviest meal of the day. Epileptics have a well-known tendency to eat hurriedly and to bolt their food. The fact that the food is not properly masticated is a great fault, but in addition bolting and eating hurriedly makes the act of swallowing frequent, and this act is a well-known source of exciting an epileptic seizure. The factor of overeating must not be overlooked in explaining the frequency of seizures at the time. The excessive degree of auto-intoxication at this period more than compensates the moderate degree of cortical inhibition still present and not in evidence in the early morning hour period.

The hour before retiring is the period of least frequency (7 P.M.), and this is quite in accord with the well-established physiological law of "good feelings" at this time and particularly the inhibitory control shown in the insane in which, on the eve of recovery, the first lucid periods occur at the hour before retiring (Clouston). The application of sedatives at the periods of greater hourly frequency invariably causes a false period to be established if sedatives alone are employed. In addition to the bromides the treatment must be to eliminate and subdue the initial causation.

Epileptics do not meet with serious accident while earnestly occupied, or, at least, not until such occupation becomes unconscious or largely automatic in character. That idleness and indifferent occupations are to be discouraged for epileptics is well known; work should be simple in character but not monotonous.

Epileptics rarely need hypnotics but are nevertheless light sleepers especially when not under great sedation. They are subject to frequent disorders of sleep and particularly liable to be great dreamers, an index to the soundness of sleep. Chloral and its allies owe their beneficial effects

* Probably, for many reasons this function is in the possession of the second layer type of cells, so-called sensory layer.

in the nocturnal types of the disease more to a hypnotic effect than as a cardiac and vascular depressant. The bromides, the exact action of which in the epilepsies is not known, however, we know they diminish the afferent impulses to the motor cells in the cortex and therefore aid inhibition.

To recognize the existence in general terms of a daily rhythm in epilepsy is of practical importance for obvious reasons, and especially to those with whom the care is immediately entrusted; particularly for guarding against accidents and injuries at those periods of greatest liability for attacks. This suggestion has most value for epileptics without known periods of liability to attacks. The agents that are employed to arrest or delay attacks are as much of our common experience as are their general inutility when indiscriminately used even when a sufficiently prolonged aura presents itself. We must, therefore, continue to insist upon a broad, comprehensive, carefully detailed, continuous plan of treatment, however empirical at present it may seem to be.

To summarize.—This study of 150,000 seizures shows that there is a more or less definite daily rhythm in the epilepsies, in the early evening, noontime, and in the early morning, which roughly divides the 24 hours of the day into eight-hour periods. There are also smaller or secondary rhythms.

The interpretation of the rhythm is explained on the basis of cerebral fatigue and the accumulation of waste products at these periods which produce auto-intoxication and which in turn exhibits itself in seizures during light sleep and during the day when the loss of cerebral inhibition is greatest. Secondary and contributing factors are: manner of living, diet, exercise, occupation, sedatives and the character of the epilepsy.

62 West Fifty-eighth Street.

## ON THE PATHOLOGY OF EPILEPSY.

BY ADOLF MEYER, M.D.,
OF NEW YORK.

All our knowledge of human reactions, and so far as that goes, of practically all biological reactions, is symbolic and relative. We can study various types of reactions and learn to distinguish them, and find the conditions under which the reactions take definite forms; but we cannot understand them as we understand the striking of a clock. We can learn to build a clock and to see how point by point, wheel by wheel, the parts are brought into connection and that the work of a spring and perhaps the regulation by a pendulum bring about the definite result. In biological observation the data of organization remain an ever-puzzling question. Experience of physics and of chemistry furnish the material for *analogies;* perhaps they actually explain certain components of the whole reaction, as the theory of statics and mechanics explain the working of the joints. But behind it all we see that the entire equation is made up of many unknown factors, among which the known principles play a very modest part. This is natural enough. All knowledge is the result of analysis and rearrangement of experience and our theoretical sciences are made up of what is most easily analyzed and compounded again in experiment, and that mostly on materials which are used for technical purposes. As soon as we leave physics and chemistry and step into biology, many x's and y's of our equations become irreducible and all attempts to ignore this and even to make electricity or the more modern theories of osmotic pressure, or the yet more modern combination of the two a panacea of explanation of biological facts, leave something like a bad taste of unripe fruit.

We can, of course, make absolutely correct calculations even if we assume the living being to be an unknown but definite quantity and introduce into the equation merely such factors as are actually understood in their relation to the rest of the total being and its manifestations. The usual blunder is that we put some physical or chemical factor into the equation without considering that we really invade and change the first which is no longer quite identical with the biological entity without the reaction which we single out. Thus we hear uric acid spoken of in relation to epilepsy almost as if it did not belong naturally to our economy, and as if we knew all about it in a large number of people.

Of all calculations in pathology, those on epilepsy have proved most elusive. Its chief manifestation, the convulsion and its equivalents, is as puzzling to the physician as it is fear-inspiring to the layman. Theories of its nature have been attempted and we have many names for them. The fact is that it is as little open to an absolute understanding as any other, even the simplest, "spontaneous" motion. We must take it just as one of the *types* of puzzles of largely spontaneous motion and be contented with establishing as far as possible, the conditions under which it occurs. In this respect, there is indeed a great deal that is worth knowing.

The first fact is that it is possible to recognize many types of manifestation of this kind of puzzle, and that some types belong more closely together, so as to form distinct natural groups with definite conditions. Thus ordinary observation allows us to distinguish epileptiform conditions from so-called idiopathic epilepsy; but distinctive marks which would point to the special origin of the type are often enough absent. If we had time for a broad review we should have to draw into our scope of analysis: subagonal twitchings, especially of animals; the convulsions of children, called eclampsia: the results of mechanical or electric excitation of the nervous system, which vary in the different animal species. A special type can be produced in the guinea-pig and in these according to some observations is even directly transferred to the young; temporary convulsions are variously produced in higher mam-

mals; differences depend in part on the architecture of the nervous system of each species; in line with these we mention the focal irritations by special lesions in the brain of man, either focalized as in trauma or tumor, or more diffuse, as in general paralysis, etc. Next we have the group of toxic convulsions (alcohol, absinth, ammonia, uremia, and diabetes). Further, the convulsions in hysteria and in catatonia, in part of psychic origin. There is finally left a large group, not further analyzed, the idiopathic epilepsies.

We see from this that convulsions are a very common form of neural action. Its study as a neural action is a dry field, but all the more important for the discovery of distinctive diagnostic types. The description of these facts properly belong to the clinician. Important positive and negative facts are brought forth by the autopsies, mostly in the direction of localization of so-called provoking lesions, or showing what we must consider effects of epilepsy, or pointing to special constitutional peculiarities. A combination of the clinical facts and the anatomical evidence together is needed to form the material for a pathological consideration, for a digest and if possible experimental investigation of the nature of the disorder and the conditions in which it appears.

Owing to what seems to me, a short-sighted way of looking at the facts, the evidence from the autopsies is looked upon as more than manifestations of the disease, as directly demonstrative of the nature of the disease. Yet nowhere more than in epilepsy do we find the need of a more modest sizing up of the anatomical facts. They are not any more nor less "pathology" than the other manifestations of the disease, usually called symptoms. They are morphological symptoms and in order that we shall get at the nature of the disease, they must be classed with the symptoms for what they happen to be worth, and the deductions must come from cautious elaboration of all the facts, if possible with experimental proof of the conclusions.

As a concession to the current manner of division, I briefly state what morphological facts we have: In a large number of cases there are lesions in the nervous system. Among these many of those of the cerebral cortex are most probably points from which the "discharge" begins, so-called provoking lesions, many of which can be diagnosed in life. There are, however, cases of so-called idiopathic epilepsy in which such provoking lesions are found only post-mortem, so that any cautious observer will refrain from supposing that during life it is possible to distinguish all the cases with a provoking lesion from others which would be idiopathic, unless one has a very accurate history. By far the largest number of findings are, however, more probably incidental, not directly provoking lesions, or at least not primary.

From my autopsies[1] I mention as provoking lesions which were not diagnosed during life: a case with a pea-sized calcareous nodule in the pia of the Sylvian fossa, probably a residual of a tubercle; and a case of moderate hemiatrophy of the brain; further two cases of senile epilepsy with very small cortical foci of softening. More usually the primary lesion was diagnosed and accounted for by the early history of the patient, as in a number of cases of infantile hemiplegia and traumatic epilepsy.

Besides what might thus be called primary lesion—a disorder existing before epilepsy broke out or with which epilepsy came on—there are frequently small foci of softening in the temporal lobes, sclerosis of the cornu ammonis, an occasional glioma of the temporal or occipital lobe, remnants of contusions of the pia, and not infrequently fresh ecchymoses around the temporal lobes, after a status epilepticus, *i.e.*, effects of the frequently violent falls and the like. The rôle of the sclerosis of the cornu ammonis is not easy to decide; but there is no doubt that it also occurs with general paralytics with severe attacks,[2] and rather too often in epileptics who have other certainly primary provoking lesions. Summing up the facts about coarse lesions, we must admit that we know of no lesion which inevitably causes epilepsy; nor of any sufficient reason why the one lesion should and another should not, except that lesions which imply frequent irritation are most apt to be epileptogenous, especially adhesions of the convexity.

Histological findings of the brain yield little that could be called causative. The occasional gliosis of the cortex discovered by Chaslin and Bleuler, and corroborated in some cases by Alzheimer,[3] Weber[4] and others, and the nuclear changes shown by Bevan Lewis, are not explicable, except as a secondary condition. Summing up the general pathological evidence furnished by anatomy and histology of the nervous system, we find that in a certain number of cases we may say that the patient had a sufficient morphological cause for epileptic attacks of the nature of a provoking lesion, and that in some cases dementia is accounted for by gliosis or secondary lesions. But in no case can we say that the patient must have had epilepsy, or with more than some probability what the attacks were and how often they appeared and with what influence on the mental and physical conditions.

Post-mortem evidence of a very interesting character and probably coming rather nearer what is needed for the explanation of the epileptic constitution, is furnished by Ohlmacher.[5] His finding of a persistent thymus and of the lymphatic constitution cannot be accidental, but are difficult to assimilate directly with an explanation of epilepsy as a whole. It would suggest the eminently constitutional character of epilepsy. The lymphatic constitution as such remains to be explained, as well as rachitis which Ohlmacher makes responsible. We further refer to the frequent recurrence of the statement that the large blood-vessels were found abnormally small.

From the observation of patients during life, a wealth of facts awaits digestion: The evidence of constitutional peculiarities and their explana-

tion including especially functional traits, such as Sommer's[6] interesting demonstration of characteristic tremor-curves even between the intervals, the many types of convulsions and equivalents, including irritative, inhibitory and paralytic symptoms, the manifestations of metabolism, and the condition of the blood and urine, and the peculiar reactions to dietetics, therapeutics and other more or less experimental influences such as serum therapy.

If we understand by pathology the digestion of all the facts of observation, clinical and post-mortem, and the further analysis and, if possible, the demonstration of the correctness of the inferences by experiment, we can naturally not attempt a summary in ten minutes; but I wish to point to some of the researches of the last five years, which are most fundamental, and if not explanatory of epilepsy, as such, marking a progress in our knowledge of the mechanisms involved.

1. The neurological side. Prus[7] shows that cocainization of the cortex makes fits by electrical stimulation impossible, so that he concludes the stimulation of sensory elements of the cortex is essential to start any fit. He also furnishes what seems to be a key to the many discrepancies in the experimental study of the fit in animals. He points to many irregularities in the irradiation of the discharge over the cortex and shows that not the pyramidal tracts, but the tegmental motor paths are the carriers of the impulses from the cortex to the segmental nerve-complexes.

This is one of the facts which is bound to change our schematic views concerning the pyramidal tract and make intelligible the claim that the tonic spasm of epilepsy is produced from irritation of the tegmentum of the midbrain and pons; evidently v. Monakow's tract is involved, and the whole mechanism to which it belongs.

But even with this elucidation, we are not carried beyond the long recognized conception of Nothnagel and others that only in a small number of cases is there a sufficient cause for the attacks themselves (as after injection of absynthe or in uremia or diabetes, or after deep faradic stimulation), and that for the ordinary epilepsy with or without a provoking lesion, we must accept a special disposition for convulsive discharges, very general in infants, but more limited to the epileptic in the adult.

The idea of Kocher that the epileptic attack is due to intracranial pressure is refuted by Bier,[8] who did not produce fits by sudden increase of the pressure by temporary strangulation, even of epileptics.

2. The second line of research is that of the relation of metabolism and fits.

This is the line to which most attention has been paid during the last few years. I do not belong to those who consider optimism about pathological chemistry and its prospects in general pathology necessarily premature. But I am equally sure that by far the larger part of chemical research concerning epilepsy operates with very small safe substance in a very large equation full of unknown quantities. And the worst of it is that the methods available seem to be open to so many errors. The literature is unbearably tiresome and contradictory and the results far from encouraging. There is hardly a substance in the urine which has not been made the beast of burden of the great puzzle of the sacred disease. Remarkable constituents have been isolated and in one especially advertised instance they were ultimately found to be simple ammonia; dietetics have been invented by the dozen, animals have been injected with doubtful substances by the hundreds; and it would seem that the more work there is, the more confusion. Wherever I turn to conscientious physiological chemists, I meet with reserve and frank admissions of ignorance, and frequently with much evidence which goes against the justification of the methods used.

With all these reserves, I consider research in this line worth undertaking, even if it were merely to get the puzzle out of the way. The following summary gives some idea of the type of work. Most of the investigations are one-sided. Matters which to one writer seem all important are found not to be considered at all by others who again extol their own hobby. The reason for it all is that the work involved for a complete quantitative estimate of metabolism goes beyond the amount of work which the dilettante can give; and if anything fundamental is to be gained, it must be put into the hands of sufficiently equipped research stations.

Most of the investigations turn around the nineteenth and twenticth century editions of humoral pathology, the theory of autointoxication. We may classify the studies into those with chemical analyses, and those of simple toxicity, and finally those of the possible production of antitoxins.

The numerous experiments of toxicity by the French and Haig's claim that uric acid is retained, gets into the blood and produces the attack and is then eliminated in larger quantities, prompted Krainsky[9] to study the metabolism of a number of epileptics. He found that when the daily amount of uric acid is 0.6 to 0.8 grams, there is no attack, but a fall below 0.45 is usually followed by an attack. Means favoring the excretion of the uric acid have, however, no influence. The amount "retained" is usually made up for after the attack. Couvreur[10] found some such relation in only four out of ten cases. The diminution may be noticed three to five days before the attack, but the amount may sink below 0.4 or even 0.35 without a fit, or fits may come on without a diminution below 0.4. If the deficiency is made up for at all, it usually takes several days. Caro[11] corroborates Krainsky's findings in his case, while Putnam and Pfaff[12] did not in their two cases.

Apart from the curve of uric acid and phosphorus Krainsky saw no regular correlation with the disease-curve. Galante[13] found, however, a regular appearance of 0.05 to 2 per cent. of albumin after the fits and a parallelism of this albumin with amounts of indican.

The chief hold for the autotoxic theory was

the experiment with injection of blood and serum from epileptics. Krainsky had positive results on rabbits and incriminated carbamic acid. Binswanger failed, and since then the majority of the conscientious experiments of Herter,[14] Roncoroni,[15] and Bratz and Hebold[16] have discredited the early claims of the French writers. Bratz and Hebold even made their injections on animals from alcoholized parents and on a dog with a brain-lesion without any typical result.

Concerning the toxicity of urine we can practically say that the injection test is as contradictory as it is of doubtful bearing. We know how difficult it is in man to establish satisfactorily the mode of death and how many precautions are necessary. In the animals of which we read the report of death after injections, there is hardly an intimation of an effort at a careful autopsy, and no sufficient evidence for the nature of the influence of the injected material.

It would seem quite fair to-day to say: With the attacks of epilepsy go expressions of an abnormal state of equilibrium, evidenced by malaise and abnormal metabolism. Auto-intoxication is not demonstrated. The facts taken for evidence of autointoxication are not linked in a convincing causal chain. The explanation of the occasional toxicity of urine and blood for animals is still wanting, and the occurrence altogether too irregular. It is suggested that it might be as well the mere expression of the condition during and after the attack and not the cause.

This negative attitude may be surprising in the face of the assurance of the latest phase of research on epilepsy represented by Bra[17] (who has found his neurococcus before and during the attacks of epileptics and has produced convulsions and death in status epilepticus in rabbits by the subcutaneous injection of the cultures), and the enticing communication of Ceni,[18] which is probably all the more fascinating because it seems to give therapeutic promises. Injections of serum from epileptics have been found by him to reduce the number of attacks in six cases, to cure two relatively recent cases, while two cases got worse. His theories, which are merely a transcription of his empirical results—are easily accessible and require no repetition here. Time will show how they will rank in the light of longer series of observation.

Somehow all therapeutic procedures in epilepsy have demonstrated a remarkable psychic factor, which always bring to my mind the experience of Dr. T. H. Gage, in Worcester, who, after his fifty years' connection with the two hospitals for the insane, has given me some very interesting accounts of the temporary influence of optimism on the part of physician and patient in various waves of new treatment in epilepsy.

We can say now that epilepsy is a disease about which there is a large material of safe empirical facts. Their use has led to a remarkable improvement of the condition of epileptics and their management, and if we wish to properly observe everything that is empirically established, and a guide for action, there are even now good chances for better utilization of what we know.

From an explanatory point of view, pathology, or scientific medicine, has added little and it does not seem to give much immediate promise. The factors, the remote etiology and the constitutional proclivity to epileptic discharges, are not very accessible to the young sciences. It is all the more necessary to lay a good foundation of carefully collected empirical facts to give a good balance to what scientific research is undertaken. I cannot suppress a feeling of self-reproach which ought to be of some use to those who direct the management of epileptics. Epilepsy is a huge field and requires an excellent system for conscientious and exhaustive observation. In my crowded clinical work, the epileptics have rarely found that exhaustive attention which they ought to get. Even in the autopsies where hurry is not the rule, I must have overlooked many things to judge of the percentages shown by men who were looking out for points of special interest to them. This makes me inclined to think that momentary interests are likely to make observation one-sided and surely put the patient at a disadvantage. Only a very systematic arrangement of the work will avoid this. With this in view I conclude.

1. The frequency of nervous lesions in epileptics is difficult to establish. The ordinary examination is too open to oversights, and must be very systematic in order to justify the verdict of negative findings. The great variation in the number of sclerosed cornu ammonis, diffuse gliosis, small foci of softening quoted by various authors, is certainly to a large extent an expression of variable attention, a picture of the psychology of investigators rather than of the distribution of facts.

2. Concerning the chemical investigations, the same psychological factor of personal interest is even more deleterious to a fair comprehension of the facts. The truism that observation of the rules of hygiene in every direction is a great factor in the management of epilepsy, is decomposed into innumerable currents of interests. Nothing short of unprejudiced and complete series of investigation will help us here, and also a much greater conservatism with complicated methods such as the tests of toxicity, the results of therapeutics, etc.

3. All these conditions are difficult to attain except in sufficiently equipped institutions for which funds should be made available by the State, and by scientific corporations, so that they may work free of the need of sensational results, create a sound basis in clinical work and systematize the investigation according to methods which can be admitted as safe and fruitful.

To what extent this had best be carried, is a question requiring much judgment. The one thing is certain—and every move in this direction should receive credit and encouragement—that institutions should be given a chance and should even be put under the obligation of doing justice to medical observation, of promoting the medical

interests of its physicians and of laying a good foundation of experience, such as the isolated practitioner can never get for himself. On such ground, more delicate investigations will find a healthy soil.

## THE LEGAL AND SOCIAL STANDING OF THE EPILEPTIC.

BY EDGAR J. SPRATLING, B.S., M.D.,
OF FORSYTH, GEORGIA.

AVOIDED by man and seemingly forgotten of God, the epileptic of all humanity is the most pitiable and the least pitied. Periodically beyond self care, often dependent upon his fellows for the preservation of his body, ever haunted by the awful doom that blights his very soul, he cannot see even a silver fringe to the cloud that obscures his life. Yet we of the law ignore him, letting him pine in prison or perish on the gallows; we of the pulpit draw our cloth closely to avoid contact in passing him; and worst of all, we men of medicine gaze a moment then turn away muttering, "hopeless, disagreeable to handle." Surely fate has done its worst when it casts the net of "falling sickness" upon mortal whether man or beast. It is our simple humanitarian duty to loosen the knots of that net.

The conditions we face are these: (1) Legally the epileptic is held rigidly responsible unless by rare change he proves irresponsibility at the specific time; (2) socially he is held to hard and fast responsibility, consequently ostracized; (3) the few who have studied him intimately know that morally he is practically always irresponsible.

Now let us see what the law has done toward lightening his burden of existence. In the Eastern States of our Union he has been studied and his condition is beginning to be somewhat understood and occasionally allowance is made for him in courts of justice in arriving at an equation of moral right and wrong. We say occasionally, advisedly, for the mental aberration must be self evident, else the unhappy victim becomes yet further accursed as a social scapegoat. Very often even here in our learned East does the law see the criminal in mirage where the patient exists in reality. In the West and South more haste and less justice is seen. There the lunatic sometimes gets deserts; the epileptic rarely if ever. It takes wealth with its settled conditions of learning and culture to make liberality; further there must be a high average of intelligence to be liberalized, else wealth itself will prove impotent. In the hurried civilization of the West, and in the South with its generation of social revolution, added to its terrible incubus of negroes, the quiet deliberate justice of the East is yet impossible. Hence the greater responsibility rests upon the East in experimenting, trying and weighing till basic conditions are reached and precedents set.

What a blot the present status is on our civilization. We think of our fathers as inhuman for stoning the leper, our children will think of us as cruel and point to our dealings with the defective, especially the epileptics, as an example of man's inhumanity to man. Only two States in all this land of lavish liberality and boasted enlightenment offer sanctuaries for the refuge of the most helpless, hopeless and unhappy of their defective children. All other States say in effect, "become either a criminal or a lunatic and then I'll cheerfully assume your burdens, but as a helpless, hopeless epileptic I'm not concerning myself about you. I'm not trying to save you while there is yet chance of making you an economic factor, however willing I may be to preserve you as a social ulcer." Is there in all this realm a harder fate or a fate more hardly dealt with?

When that lowly priest in the valley of the Rhine offered himself to be the Moses of this most benighted section of humanity he put to blush the charitable world and soon had blazed the way for the truest benefactory legislation ever graved on statute books. He and his flock have treaded a path, tortuous and stony in places it is true, to the elysian field of comparative contentment. And the sight of those anxious social outcasts crowding to his hearthstone and tapping at the door of his heart crying "Save me ere I sink," makes one of the most pathetic chapters in all the history of suffering humanity. At his fireside they found warmth, and in his heart they found devotion in such generous measures that their frozen natures were warmed till they became all but happy. Not happy, no, for Jove in anger at the murder of Iphitus swore that neither Hercules nor any of his epileptic ilk should ever reach that. Mentally astigmatic, spiritually strabismic, the clear straight rays of happiness are for him distorted.

Even after Bielefeld had thrown its enlightening rays on the world for nearly a generation, Ohio as a pioneer took cognizance of the epileptic not as such but as a lunatic, and founded a separate asylum not as much for his care and his pleasure as for the *comfort of the other lunatics.* Think of it, because the insane epileptic was an unpleas-

ant associate for the maniac was he segregated! Nevertheless he became the recipient of a disguised blessing, for the action of Ohio put alienists and neurologists to watching and thinking, culminating in the genius-like flash, that brilliant patch of sunlight, Sonyea.

When New York State founded for sane epileptics Craig Colony from the public treasury, and maintained it by public taxes, the millennium of charitable legislation seemed nigh at hand. There the epileptic and not the lunatic is cherished and studied and remodeled for a scientific problem.

As a result of all this awakening we will ere long see the scales of justice balance even with an epileptic in one pan. It will not rest then with indifferent juries, but the expert guided by definite standards will say when justice is satisfied.

But as yet we are many, many rounds beneath that supreme height, and frankly stated our standing ground to-day is this: New York and Massachusetts, only, recognize the helplessness of the epileptic and extend to him an official hand ere he sinks hopelessly into insanity. Among nearly all other peoples he is simply a disagreeable person, a crank, a pauper, a lunatic or a criminal as circumstances seem to indicate. He is a veritable briar in the social rose garden, an incubus on his friends, a blight on his family, a burden to the community, an annoyance in hospital or asylum, a black beast in prison. No wonder he is such a nightmare in the courts of justice. And doubly strange it is that no real scientific and concerted action to bring order out of chaos has been taken by our medical fraternity. Why is it that precedents have not been established for future guidance?

An epileptic who commits crime should be deprived of liberty during the continuance of his disease, but he should very rarely, if ever, have the stamp of convict placed upon him, for the convict should be a criminal by intention, while the epileptic should be presumed to be irresponsible, therefore incapable of criminal intention till clearly proved otherwise. As the law by omission, and practice by custom, now stand he is presumed to be responsible till proven not epileptic but insane. How unjust, for while the epileptic state lasts it constitutes one of the very worst types of mental unbalance but being often of short duration with clear intervals between attacks the public and the bar, yes, and often the court, fail to grasp the idea of periodic actual mental irresponsibility. In the eyes of the law this means inability to distinguish right from wrong at the time of examination or trial and not often at the moment of the overt act. The test of mental irresponsibility really ought to be not the faculty of distinguishing right from wrong, but the power of resisting wrong as opposed to right. We know that the epileptic may be totally vacuous mentally this minute and markedly alert the next. That statement is patent to those who have studied him intimately, but apparently incomprehensible to those who have thought nothing of the problem.

It is indeed a hard fate that the epileptic must suffer all the damage of the insane, bear the cross and show the hall marks of insanity, and yet wear the convict's stripes. But such is the fact to-day. The next generation will see that changed. The law will require their segregation, but not convict imprisonment.

Black as the legal status has been painted, yet darker coloring is needed for the finishing of the social picture. Ostracized becomes a light word, outcast but little worse, despised is more fitting. The family hides him from the world, keeping this awful skeleton well closeted, and where possible leaves him to the tender mercies of hirelings.

The epileptic as a rule is not an attractive personality, usually wearing in face and figure, in the very atmosphere about him the trade-mark of the most unfortunate. Careless in speech, prone to exaggerate, illogical in conversation, irritable in controversy, erratic in ideas, he makes an all round disagreeable comrade. Suspicious, improvident, forgetful of the past, indifferent to the present, careless of the future, he makes an utterly undesirable friend. As the preacher's protégé he causes the ministerial heart strings to tighten; as a client he provokes his lawyer into losing faith in humanity; as a patient he all but forces his doctor to dislike his calling. Not welcome as a private guest, not wanted in public gatherings, even his own family holds its conferences without him. The confidant of no one, in close companionship with only his own perverted imaginings, no wonder in brooding over his fate he sees the world all against him. Truly the thorn and not the petal of the rose, the burr and not the down of the thistle, go to make his couch.

We ask each other over and over again if there be a remedy for all this? No, the very conditions say there is not. The best we can hope in the reasonable future is amelioration and that will come by segregation in colonies of course. There he can be suitably clothed and fed, humanely treated, and his energies directed into profitable as well as congenial channels, thus minimizing the curse of his disease. The very nature of his disease makes him a social incubus and our efforts should be to lighten the weight of his burden.

His moral irresponsibility is a fact beyond controversy, for his acts are at times purely automatic; nor is this state brought on by his volition. Therefore, it becomes self-evident. Because of the ofttimes similarity between alcoholic and epileptic stupor, the public fails to make the necessary all-important distinction. That difference is this: the inebriate is mentally but not necessarily morally irresponsible in that he voluntarily induced his stupor. The epileptic's stupor is involuntary, hence completely obliterates his moral as well as mental responsibility.

We can place the average epileptic in worldly setting as follows: forbidden socially: unwelcome in court except as criminal or lunatic. Truly this disease puts the porcupine's armor on its unhappy victim. He becomes a veritable noli-me-tangere, neither man nor beast approaching him unscathed.

If Nirvana be a reality, if there be a dreamless sleep with no awakening and rest eternal, let us not begrudge him it, for surely happiness will not come nearer.

In a little corner of this chaotic picture of melancholy figures let us remember to place the sweet placid face of that rarest of individuals, the contented, almost happy epileptic; whether that contentment be a water mark of insanity or whether the heart has been touched by a love higher than human we can never tell. But we all who have dealt much with the epileptic have seen one or more of these pitiable, pitied, lovable and loved characters. I have been told that at Bielefeld and Sonyea one sees many of those faces; if that be true let this Association rest not, nor look backward, till every nation and every State may point to such a place as its chief ornament.

## THERAPEUTIC SUGGESTIONS IN DIPHTHERIA.

BY LOUIS FISCHER, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS, ETC.

The specific treatment of a case infected with diphtheria consists first and foremost in giving it *the required dose of antitoxin.* The dose depends on the severity of the infection. The usual amount required for a very mild case, of a child from one to five years old is 1,500 units. If there is no effect noticeable within twelve to twenty-four hours then the second injection of the same quantity should be repeated. A child five to ten years of age should be given at least 2,000 units at its first injection to be followed in twelve hours by another injection of the same dosage if there is no amelioration of the symptoms.

When we are dealing with a severe toxemia with marked general depression and large pseudomembranes in the throat, then at least 3,000 units of antitoxin should be injected in the beginning. When the cervical lymph glands are enlarged and there is slight or severe evidences of stenosis then at least 3,000 units should be injected in the beginning.

*Indications for a Second and Third Injection of Antitoxin.*—If twenty-four hours after the first injection there is no visible effect on the pseudomembranes, if the child is not brighter, if the appetite is poor and if the heart's action is very poor, in other words if there is no visible improvement, then by all means inject a second dose of antitoxin.

The necessity for the third injection depends upon the pulse, temperature and the condition of the glands of the neck, also upon the macroscopic condition of the throat. If no improvement exists then the third injection is imperative.

*Laryngeal Stenosis.*—It is always a safe plan to give a large injection of 3,000 units and if the stenosis does not disappear in twelve hours, then I give an additional injection of 1,500 units so that in all 4,500 units can be injected during the first twenty-four hours.

The above treatment with antitoxin will be serviceable when we are dealing with a pure Klebs-Loeffler infection, but there are a great many cases in which this is not so.

*There are contributing factors leading to a fatal termination.* First and foremost is the presence of the streptococcus in addition to the Klebs-Loeffler infection. In these mixed infections we have in addition to the general diphtheria, a distinct streptococcemia. In these cases antitoxin is inert as regards the streptococcus. We frequently have bronchopneumonia, nephritis, arthritis, otitis, and local abscesses due to the invasion of the streptococcus. To neutralize such mixed infections we require besides the Klebs-Loeffler antitoxin a streptococcus antitoxin or a potent antistreptococcus serum.

*The bacteriological findings will therefore be the guide in the future in determining, first, whether a culture from the throat shows a mixed or an unmixed infection and in addition to this bacteriological examination, the blood must be examined to determine the presence or absence of a streptococcemia. The treatment must be based on scientific data, hence, it should conform with the result of what is found by culture from the throat and by the thorough examination of the blood.*

If we can inject a sufficient quantity of antitoxin to stimulate cell activity and neutralize general toxemia, then we give our patient the greatest opportunity to eliminate this deadly poison and to begin convalescence.

*The ordinary shortcomings* that are most frequently met with consist of, first, placing too much reliance on the specific nature of antitoxin regardless of other vital necessities. In this infectious disease, where there is marked leucocytosis and other evidences of subnormal hemic conditions, the *indication next to antitoxin is for restorative treatment.*

*Mouth Feeding.*—As a tissue and blood builder *no medication equals food.* It is, therefore, imperative to support the general nutrition by proper feeding. Milk diluted with some cereal decoction, like oatmeal, barley or rice will be better borne than pure milk alone. Sometimes it is necessary to partially peptonize to render it more absorbable. If the child is old enough the yolk of a raw egg can be added to the milk. Concentrated beef broth, chicken broth, clam broth or oyster broth should be thought of. When feeding, once in three hours, it is a good plan to give some of this concentrated broth, followed in three hours by a milk feeding, and so alternate. In this manner we give our patient milk once in six hours. Acid fruits, such as oranges, lemons, grapes and cranberries are very well borne. When acid fruits are ordered they should be given an hour before milk feeding. Older children can be given raw scraped steak, calf's foot jelly, and ice cream which is nutritious and pleasant. When it is *difficult to feed by mouth* owing to excessive vomiting or to anorexia, or where intubation has been performed, then it is a good

plan to let the stomach have absolute rest and to depend on

*Rectal Feeding.*—No more than two ounces should be injected at one time.

Milk, predigested, ..... 1 ounce
Starch water, ..... 1 ounce
Laudanum ..... 1 minim

To be injected slowly through a colon tube, after both colon and rectum have been cleansed by a soap-suds enema.

If the small nutritive enema is well retained then we can repeat the injection once every four hours, and add the yolk of a raw egg to the above formula of milk, starch and opium. Next in importance to giving the proper dose of antitoxin is the nutrition of the body which has just been considered. To assure proper assimilation of food requires attention to the bowels. The elimination of toxic elements can only take place by means of the bowels, kidneys and skin. Normally in febrile conditions there is a general torpidity of the emunctories. Thus it is apparent that a dose of calomel, citrate of magnesia or an alkaline solution like the milk of magnesia or a laxative mineral water, will aid in the performance of these functions.

*Local Treatment.*—It is advisable to remove the putrid membranes from the nose and throat and also the catarrhal discharges. To do this mechanical treatment consisting of the cleansing of the nose with a salt solution of the strength of one dram of table salt to one pint of water is useful. A weak (½ per cent.) solution of permanganate of potash solution can also be used to cleanse the nose by the aid of a syringe.

Septic products in the nose and throat will frequently lead to a fatal termination. Their presence is a constant menace to the blood by inviting toxemia. In addition thereto they give rise to fever and not infrequently septic material will find its way from the nose and pharynx into the Eustachian tubes causing abscesses. If neglected it may lead to mastoid involvement and brain abscesses or to septic meningitis, with *little or no chance of recovery.*

By studying the usually enlarged lymph glands, it is surprising to see what good result is apparent after cleansing the nose and pharynx.

*Local Treatment of the Pseudo-Membranes.*—The solvent effect of local remedies I have never been able to see. When papayotin has been used, I have been disappointed in its effect. Creosote vapors, by adding a dram of beechwood creosote to a pint of water and allowing the air to become impregnated with the vapor has shown some good in a few instances. Lugol's solution of iodine (half strength) applied by means of absorbent cotton, can be recommended. A steam atomizer containing a weak solution of (two per cent.) sulphurous acid is recommended by Dr. Nicholas at the Riverside Hospital. The latter has been used by me and certainly can be recommended when there are extensive necrotic patches. It is far better than the peroxide of hydrogen. Other local treatment which I have used with benefit is the inunction of unguentum Credé into the cervical glands. Rub in at least fifteen to twenty minutes two or three times a day. An ice-bag worn continually can also be recommended when there is an extensive edema.

*Hygienic Treatment.*—One of the most important adjuncts to the treatment consists in admitting fresh air. A patient with diphtheria should have all visitors excluded from the room. A good current of air should be admitted night and day, and thus oxygen so necessary in this disease is secured.

Oxygen is indicated and required when there is the slightest evidence of cyanosis. It will also relieve dyspnea when present. It is especially indicated during bronchopenumonia which so frequently complicates diphtheria.

*Fever Treatment.*—It is a wise plan to exclude antipyretic drugs during the treatment of fever in diphtheria. The best antipyretic measures consist in sponging with evaporating lotions such as alcohol and water or acetic ether, locally. Cold packs and flushing the bowel with cold water are very serviceable in some cases. When high fever, due to pneumonia, to nephritis or to any other complication exists, the same should be treated as though the disease existed independent of the diphtheria.

When fever exists and the child cries continuously then the ears should be examined. Frequently an otitis media will keep up high fever until the drum is ruptured. Ten to 20 drop doses of sweet spirits of niter are valuable if given several times a day. During the febrile stage of diphtheria calomel in $^1/_{10}$ to ½ grain doses, repeated several times a day is a useful adjuvant in fever treatment.

*Stimulation.*—Owing to the depressing effect of the diphtheritic poisons, stimulation should begin early. Strychnine $^1/_{100}$ gr. for a child one year old, repeated three or four times a day. The dose can be gradually and cautiously increased until a systemic effect is noticeable. Children will tolerate very large doses of strychnine just as they will tolerate very large doses of whisky. They can be combined. Tokay wine, champagne and coffee are valuable cardiac stimulants. Caffeine citrate and sparteine are also serviceable for enfeebled heart's action. The prognosis of a case of diphtheria is certainly better in a case where the heart has been supported until the toxemia has passed away.

65 East Ninetieth Street.

## A REPORT OF A CASE OF SPINA BIFIDA; OPERATION; DEATH.

BY CHARLES GREENE CUMSTON, M.D.,
OF BOSTON, MASS.

A. G., aged eleven months, was seen for the first time in the middle part of August, 1902. The family history was as follows: the father had contracted syphilis six years previous to his marriage but the mother, as far as one could ascertain, had never presented any signs of spe-

cific infection. The first child was born at seven months, conception having taken place a few months after marriage. Her second child was born at full term two years after the first one and presented a hare-lip, for which I had operated when the child was three months old; in other respects the child was apparently normal and fairly well-developed.

The third child was our patient. He was born at term and the labor had been an easy one but immediately after birth a reddish swelling was discovered on its back, the mother saying that at birth it might have been the size of a tangerine orange. This tumor slowly increased in size and latterly the mother thought that it had become tender on pressure as the child cried when laid on its back or during the toilet when the tumor was brought in contact with the towel.

Examination showed an apparently strong male baby while at about the level of the fourth and fifth thoracic vertebræ directly over the spinal column was a globular tumor the size of an apple presenting a rather broad base. It was covered by normal skin from its base to about the middle of its circumference while the remainder of the growth presented a reddish-blue covering. By manual pressure on the tumor, it could be reduced to a slight degree and it was noted that when this was done the large fontanelle was made to bulge somewhat and the child became uneasy as if from pain. Crying seemed to cause the tumor to become more tense and larger.

The large fontanelle was rather tense and had not become closed as much as usual considering the age of the child. Examination of the spinal column, thorax and ribs showed that there was nothing abnormal on either side. The movements of the lower limbs seemed perfect. By a carefully conducted palpation, we were not able to discover any cleft in the vertebræ. The tumor gave rise to fluctuation which was very distinct and a diagnosis of spina bifida was made and on account of the general good condition of the boy, and from the fact that the tumor was increasing in size an operation was advised.

After carefully preparing the region for several days, ether was given and an incision was carried near the base of the tumor so as to form two oval flaps. The skin was then separated from the cystic wall by blunt dissection with the finger down to the base of the tumor. After the cyst wall had been thoroughly freed, it was incised on one side and the cavity was explored with the finger. At the time of opening the cyst a considerable amount of colorless fluid escaped and after it had become emptied the bulging fontanelle was found to be quite depressed.

Digital examination of the interior of the cyst showed that it extended into the vertebral canal by a thin pedicle which passed through a cleft of the spinous process. The cleft measured about one centimeter in breadth. While exploring the interior of the sac a solid, whitish cord about the diameter of a lead pencil was found and recognized as the cord. This was inserted into the vertebral canal and a purse-string suture was placed at the base of the sac and after tying the cyst was removed by scissors. On account of the narrowness of the vertebral cleft an osteoplastic operation to cover up the gap was deemed unnecessary so that the skin flaps were simply united by aluminum and bronze wire sutures. The child stood the operation remarkably well, although when he left the table his respiration was rather rapid and the pulse beat was 145. He rallied rapidly, however, after a subcutaneous saline solution had been injected. Twelve hours after the operation, the temperature was 38.5° C. and the child was resting quietly with a pulse of 110.

The boy continued to do well for the first five days, his temperature being nearly normal in the morning with a slight evening rise while the pulse rate averaged about 100. He took his bottle well but on the beginning of the fifth day he appeared somewhat drowsy and in the evening the temperature had reached 39° C. For the next five days the drowsiness continued, the fontanelle was bulging and very tense, the child refused his bottle and he finally expired ten days after the operation.

Post-mortem examination revealed the following: After the skull had been opened a large amount of fluid escaped which was estimated at about 150 c.c. There was some blood in the longitudinal sinus. The pia was greatly injected. Both ventricals were greatly dilated and were filled with a turbid, blood-stained serous fluid. The third ventricle was also dilated while the ependyma was very hyperemic. The gray cerebral matter was very thin and in some spots it was not markedly distinct from the white matter. The medulla oblongata and pons were markedly hyperemic. Thoracic viscera normal. Spleen enlarged and soft. Perfect union of the operative wound had taken place and no cerebrospinal fluid had escaped.

A cleft occupying the fourth and fifth thoracic vertebræ was found seated in their spinous processes and protruding from this cleft was seen the cord covered by its normal envelopes. The cleft measured just one centimeter in width. The anatomical diagnosis was spina bifida, external and internal hydrocephalus.

Of the diagnosis of spina bifida there naturally can be no doubt. The tumor had existed since birth and had increased steadily in size. It was situated in the median line and when pressed upon diminished in size, caused the large fontanelle to bulge and the child became decidedly uneasy. The question is, In what subdivision of spina bifida should this case be placed? It is quite evident that a myelomeningocele could be excluded from the start on account of the absence of paralysis of the lower limbs and more especially from the fact that the characteristic anatomical conditions of this type of the congenital defect were wanting, namely, the differentiation of the medullovascular, epitheloserous and epithelodermic zones.

Both the composite forms, namely, myelomen-

ingocele antero-posterior and ventralis could also with a fair amount of certainty be excluded because the cleft in the vertebræ is usually so wide that it can be easily detected by palpation while in the case under consideration the opening in the bone could not be made out. By exclusion we therefore only have remaining meningocele, simple myelocystocele, and myelocystomeningocele dorsalis.

An uncomplicated meningocele, as is well known, is an extremely rare type of spina bifida and in most instances in which it has been observed, it has been met with in the sacral region. My diagnosis made before the operation was that of a myelocystocele because the tumor presented a broad base and also from the fact that pressure over the cyst produced a marked bulging of the fontanelle.

As far as the indications of the operation were concerned, the necessity of an absolutely correct diagnosis was unimportant because no matter which of the two types of spina bifida was present the removal of the sac is at the present time generally considered as the proper treatment. On the other hand the cleft in the vertebræ was narrow and besides paralysis and other congenital defects were absent so that there were no contra-indications.

Considering the case all together it appeared to me that an operation was clearly indicated from the fact that the tumor was and had been steadily increasing in size since birth, and sooner or later the sac would rupture. Then again, the child was to all intents and purposes strong and well nourished and the tumor was certainly causing him a good deal of discomfort.

The operation in itself was of the most ordinary kind and when the liquid contents of the sac escaped it was noted that the fontanelle became depressed, which was proof positive that a communication existed between the cyst and the subdural or subarachnoid spaces for which reasons we concluded at the time of the operation we were in reality dealing with a case of meningocele. But by palpation of the interior of the sac our first supposition was rapidly done away with because a pedicle extending into the spinal cord could be felt and which by inspection proved to be the cord itself and could be explained as a sacculated condition of the coverings of the spinal cord. Our diagnosis was therefore changed to a myelocyst complicated by a dorsal myelocele.

In the case of a simple myelocystocele the substance of the spinal cord spread out over the wall of the sac is in most instances so reduced that its removal in no way interferes with the patient's health.

The cause of death after operation for the cure of spina bifida is usually meningitis, bronchitis, enteritis or loss of strength from the draining away of the cerebrospinal fluid. The loss of the latter is so detrimental that in a case reported by Marchand in the *Revue de Chirurgie*, in 1891, he lost a patient from this cause following simple puncture of the sac.

In our case, an internal and external hydrocephalus was demonstrated at the autopsy and should have been a contra-indication to operative interference, but the symptoms pointing to hydrocephalus were not clearly marked. The child's head was not unusually large at the time we saw him, nor could it have been excessively large at time of birth since it gave rise to no impediment during labor.

## MEDICAL PROGRESS.

### MEDICINE.

**Correlation of Alcoholism, Crime and Insanity.**—Careful investigations into the etiological factors which result in filling our jails and insane asylums shows that inebriety is undoubtedly the most important. C. A. Drew (Med. Rec., June 20, 1903) says that there were 154 cases committed to the Massachusetts State Asylum for Insane Criminals during the past two years and of these only 11, or 7 per cent., claimed never to have used alcohol as a beverage. Of these 11 cases, 3 were epileptics and 2 were well-marked cases of imbecility. Ninety-six per cent. of the cases considered themselves hard drinkers, the majority having been drunk many times. He has been led to the belief that the offspring of sound, temperate parents are less likely to suffer from alcoholic insanity, though heavy drinkers, than the second generation who may not drink half as much. Pronounced alcoholism in the parents always means examples of mental disease and weakmindedness in the children, provided the alcoholic tendency is not acquired somewhat late in life. An inebriate father is certainly a handicap, an inebriate mother is a greater misfortune, but the child of an inebriate father and mother is almost certainly doomed from its birth. It has often been proven by the most eminent modern investigations that even a moderate quantity of alcohol in the circulation will cause marked changes in the cortical neurons of the brain. Changes in the nucleus, granular bodies and protoplasm may be actually seen. Because these cells are the material basis of man's moral sense and conscience, the physical representatives of his aspirations, his likes, his fears and his will power, their harm seems to be of far greater importance than the question of the food value of alcohol or the effect of alcohol on the stomach and liver. It is a law of nature that the most highly organized tissues suffer first and most from toxic agents in the blood, so it is the moral and ethical sense which suffers first and most and is often the only manifest evidence, in the first generation, of the baneful effects of alcoholics taken in moderate quantities.

**Chyluria.**—An interesting case, in which this rare condition was present, is reported by Bécizneul (Gaz. Méd. de Nantes, May 30 and June 6, 1903). The patient, a youth of sixteen, in good health, sought advice on account of the appearance of the urine, which, in the morning, was of milky consistence and color while during the day its normal limpidity was maintained. Upon standing for several hours, the specimen did not clear; neither did filtration or centrifugation restore its normal color. Examined under the microscope, numerous fine granules were seen, the nature of which could not be determined; but upon addition to the specimen of a small amount of ether, a certain number of the granules coalesced to form globules, analogous to milk globules. The presence of albumin in large quantity was shown by the usual tests. A curious feature in the case was the fact that not only the night's repose was followed by elimination of chylous urine, but the horizontal position, maintained during the

day for but an hour and a half, sufficed to give the previously limpid urine the milky appearance seen in the morning. Out of a series of ten cases collected by the author from the literature of the subject, a like effect of the horizontal position upon the urine occurred in four. In Becizneul's case, repeated tests showed the limpid day's urine to be entirely normal; while the night's urine invariably contained the elements of chyle. A careful study of the blood and urine failed to show the presence of *Filaria sanguinis hominis*, the most frequent cause of chyluria; therefore the case is to be classed as chyluria nostras.

**Carcinoma and Diabetes.**—The relation of these conditions one to the other has heretofore met with little consideration until the recent observations of Boas were published. He came to the conclusion that in isolated cases the carcinoma seemed to exert an antagonistic influence on the primary diabetes, but as a rule no effect is seen. Another contribution has just been made by K. Oestreicher (Prag. med. Woch., June 11, 1903), of Carlsbad, who found four cases of carcinoma in 247 cases of diabetes under his care. His results agree with those of Boas. In one instance, the carcinoma appeared in the sixth year of the disease, and while in former years it had always been possible to reduce the sugar to a minimum amount by treatment, as soon as the carcinoma appeared the sugar could not be brought below two per cent. The same condition occurred in the following year. During the next year the tumor grew rapidly, and ulcerated. It was then found that the glycosuria became markedly reduced (0.5 per cent.); and the diabetic symptoms improved. In two other cases the diabetic symptoms became steadily worse with the appearance of the carcinoma. In the fourth case no connection could be traced between the two conditions. It is seen, therefore, that there is nothing characteristic in the course of a diabetes when a cancer intervenes, except that in one case an antagonistic influence seemed to have been exerted.

## SURGERY.

**Total Extirpation of Prostate.**—The various operations for the relief of the many distressing and even serious symptoms which arise from an enlargement of the prostate gland have received a great deal of attention of late, and are deserving of much more study on the part of the general practitioner. The total extirpation of the organ is considered by most people as an extremely difficult if not an impossible operation. P. J. Freyer (Practitioner, June, 1903) has been performing this operation several years and believes that the difficulties experienced by most men in their attempts at total enucleation result from their ignorance in regard to the anatomy of the organ. The prostate is in reality composed of twin organs, which remain separate in some of the lower animals, but in man they approach each other and become agglutinated except along the course of the urethra, which they envelop in their embrace. Each of these two bodies is enveloped by a thin, strong fibrous capsule which extends over the entire organ except along the upper and lower commissures, or bridges of tissue, that unite the lateral lobes above and below the urethra, thus filling in the gaps between them. This true capsule is intimately connected with the prostatic mass and cannot be separated from it except by dissection. The urethra, accompanied by its surrounding structures passes forward and upward between, and is embraced by the inner aspects of the two glands or lobes. The ejaculatory ducts do not pierce the capsule but enter the urethra through an interlobular fissure. The prostate thus enveloped in its true capsule is further encased in a second capsule or sheath, formed by the rectovesical fascia, numerous connecting bands, however, passing between the two. The prostatic plexus of veins and the larger arteries lie between the two capsules or in the outer one. In the operation described it is the true capsule which is removed, the sheath being left behind, thus preventing infiltration of urine into the cellular tissues of the pelvis. Another important anatomical fact not usually appreciated is the part of the gland usually enlarged and the direction it takes. The enlargement is principally adenomatous in character, and at first probably entirely extravesical. Its expansion, however, is limited by the pubic arch, triangular ligament and sacrum, so that it soon becomes necessary for its advance to be made in the direction of least resistance, namely, into the bladder. The sheath, which at the posterior aspect of the prostate is least defined, becomes gradually thinner as the enlargement advances until it is finally burst through, leaving nothing but the mucous membrane covering the prostatic gland. To accomplish the ideal operation, suprapubic cystotomy is performed after first thoroughly washing out the bladder, leaving the catheter in situ. One forefinger is then placed in the rectum and the other passed through the wound into the bladder. The mucous membrane over the most prominent portion of one lateral lobe, or over the so-called "middle lobe," is scored through by a sharpened finger-nail and gradually detached by it from the prostate projecting into the bladder. The true capsule of the prostate is here at once reached and by keeping the finger tip in close contact with the capsule, the enucleation of the prostate out of the enveloping sheath outside the bladder is proceeded with by insinuating the finger-tip in succession beneath, outside, and above one lateral lobe, thus separating the capsule from the sheath. The finger is then swept from without inward, above and to the inner side of the lobe, detaching this from the urethra, which is felt covering the catheter and pushed upward toward the symphysis, between the lateral lobes, which will, as a rule, have separated along their superior commissure in the course of the manipulations. The other lobe is similarly treated and when the apex has been freed, the whole gland is drawn and pushed into the bladder and then out through the abdominal wound. The ejaculatory ducts are usually torn across but that is of trifling importance. There is, as a rule, very little bleeding and this is controlled by irrigation with hot solution through the catheter. In several cases the urethra has been torn across completely and even portions of it removed. No subsequent ill effects have resulted from such unavoidable mishaps and such accidents are not to be greatly regretted. The remote results from such an operation are excellent and complete resumption of normal urination is almost always attained. Of 45 patients thus operated upon, ranging in age from fifty-seven to seventy-nine years, 40 have been successful both immediately and remotely.

**Sterilized Catgut.**—A rapid and easy method of sterilizing catgut is proposed by J. M. Garratt (Am. Med., June 27, 1903), and the gut has withstood the test in some 3,000 operations. The gut is cut into suitable lengths, 10 and 20 inches, and several of these strands are placed in envelopes of unglazed paper. The latter are sealed and marked with indelible ink or pencil with the size of the gut. These envelopes, to the number of 40 or 50, are placed in a quart-size preserve jar which has been freshly sterilized, and covered with a solution containing mercuric chloride gm. 1 (gr. 15); tartaric acid gm. 5.5 (gr. 75); Columbian spirits and ether, of each one pint. Depending on the size, the gut is left in the solution for from four to twelve hours. The jar is then drained, and filled up again with Columbian spirits and tightly closed. It is essential that the Columbian spirits be used. After the needle is threaded when the gut is to

be used, the latter should first be placed in freshly distilled water. The material has been proved to be tough, pliable, strong and thoroughly aseptic.

## OBSTETRICS AND GYNECOLOGY.

**The Indications for Hysterectomy in Puerperal Sepsis.**—A very able argument on the various means and methods to be pursued in this condition is set forth by Valére Cocq (Gaz. de Gyn., April 1 and 15, 1903), and the results of the discussion are told in the following summary: In general hysterectomy is indicated when there is a grave toxemia or when the uterus has in all probability become the chief entrance of the septic material; and in spite of all other means of treatment have been tried and the patient is still sufficiently strong to withstand the operation. These conditions are present in certain cases where the placenta has been retained and is undergoing decomposition and where it cannot be removed by the curette. Also in the case of a suppurative metritis where fibroids have undergone prolonged compression during the course of labor, degenerating, and clogging the flow of the lochia by their rough surfaces, destroying the endometrium, facilitating the reabsorption of the septic products through their great vascularity. In streptococcic septicemia the ablation of the uterus which, though macroscopically without lesion, but in reality thronged with the organisms, exercises a most happy influence on the final outlook in the patient's recovery. Cases where there is large involvement of the parametrium and the adnexa are only too often treated by ice and opium in the hope that operation may be avoided, but sooner or later the radical operation is found to be necessary to save the life of the patient.

**Conservative Surgery of the Appendages.**—Since the month of May, 1896, to the month of December of last year, Hector Treub (Am. Gyn., May, 1903) has operated upon, or treated in his clinic, 612 cases of salpingo-ovaritis. Out of these, 70 per cent. have been more or less completely cured, without operative intervention. The uniform treatment in all of these cases has been as follows: Complete rest in bed and the application of an icebag as long as there was any fever; the acute symptoms passed, warm vaginal injections (45° C.), vaginal tampon with glycerine and warm water compress (Priessnitz's bandage) on the lower part of the abdomen. The duration of treatment varied from a few weeks to several months; the average duration could be rated at about six weeks. In every case the woman considered herself cured, having no longer subjective symptoms of the disease. Out of the 70 per cent. there are about 20 who have been treated more than once in the same manner, which would equal about 5 per cent. of relapses more or less serious and in every case sufficiently troublesome to necessitate another sojourn at the clinic. In order to be certain not to exaggerate the results of non-operative treatment, it may be said that little over one-half the cases of salpingo-ovaritis necessitated no operative intervention whatsoever. The significance of this fact is clear, and it is important to emphasize it, since in these modern times, even, it is held a part of good surgery to remove the appendages when they are diseased. Massage is excessively dangerous in the cases of obstinate salpingo-ovaritis, where one is never sure of not finding a purulent focus of inflammatory intraperitoneal mass. Although the final results will not be uniform in all the cases treated by non-operative intervention, one finds that conservative treatment offers: (*a*) A danger of death which ought to be estimated two per cent. at the most; (*b*) some chances more or less great of not giving complete relief to the patient; (*c*) some chances also of being insufficient and necessitating a second operation either conservative or radical; (*d*) the certainty of not procuring for the patient a new malady, under the form of the anticipated menopause. Again: medical treatment suffices in at least one-half of the cases of salpingo-ovaritis. It being insufficient or contraindicated, one should never at the outset perform a radical operation of any sort. The first operative stage should always be posterior colpotomy. When by means of this proceeding it is discovered to be a tuberculous process, hysterectomy should be performed as soon as possible. In cases of hydrosalpinx which do not yield to repeated colpotomy, and which necessitate other intervention, and in cases in which one wishes to remedy sterility in women, the conservative operations (resection, salpingotomy, salpingo-ovarosyndesis) are indicated. Salpingorrhaphy should be reserved as an accessory operation to a course of laparotomy performed for no matter what other indication.

**Weight Wave of Menstruation.**—The record of the daily weight of four healthy, unmarried women between the ages of twenty-two and twenty-nine, and of average menstrual regularity, during a total of 23 menstrual periods, discloses a phenomenon which W. T. Belfield (Jour. Am. Med. Ass'n, June 13, 1903) terms the weight wave of menstruation. During several days, especially the first, preceding the flow, there occurs a progressive increase in weight, from 2.5 to 5 pounds, which may be from 1.5 to 5 per cent. of her usual weight. The climax of this gain is followed by a rapid loss of about half within eight to sixteen hours, and then a more gradual loss of the remainder, extending over several days. The flow begins during the loss, often following immediately on the crest of the wave, and terminates about when the weight returns to its normal lever. The premenstrual gain is due to diminished excretion, especially of water, and the rapid loss to rapid excretion, notably of carbon dioxide and water. After the weight has sunk to its premenstrual level, there may be another crescendo and diminuendo movement, lasting several days, but less pronounced. Hereafter the weight shows no constant variation until there occurs a sudden transient loss which is the forerunner of the next period. Two cases of irregular menstrual habit, exhibited the wave on several occasions when the flow was nearly or quite lacking. A woman of fifty-nine years, who had not menstruated for twelve years, showed no characteristic wave. For two days preceding the climax in weight there is often marked torpidity of the bowels and scantiness of urine; while, with the decline in weight, excretion in all channels is notably increased. The temperature curve is not constant; there is usually a rise of about 1° F. during the increase in weight and a sudden fall after the crest of the wave is passed.

**Immediate Delivery in Eclampsia.**—Statistics have shown that 75 per cent. of the deaths which take place as a result of childbirth are caused by infection and puerperal fever. The remainder are mainly due to hemorrhage and eclampsia. The treatment of the latter cases has left much to be desired until very recently. E. Bumm (Münch. med. Woch., May 26, 1903) gives the result of his extensive experience, having personally treated 112 cases during twenty years, by all the methods in vogue at different times. His observations during the past two years have convinced him that in every case where the eclampsia is seen soon after the first attack, while the pulse is good and the lungs are still intact, a favorable issue always results from the immediate emptying of the uterus. The mortality according to his belief, will be reduced to not over five per cent. by this procedure. If the cervix is completely dilated, version, forceps or, if necessary, perforation is indicated. If the cervix is partially opened, further dilatation may be best accomplished by combined version, pulling down a foot and using the breach to complete

the dilatation, and the author believes it can be done just as quickly and possibly with less danger for the unpractised, than with the metal dilators. For a closed cervix and delivery indicated at once, the vaginal Cæsarian section as devised by Duhrssen, is the method to be preferred.

**Conservative Operations in Sclerocystic Ovaritis.**—A plea for the conservative treatment of sclerocystic ovaritis is made by A. Boursier (Jour. de Méd. de Bordeaux, May 24, 1903), who holds that the choice between the radical and conservative operations should depend upon the condition of the tubes. In his belief, castration should be resorted to only when the tube is seriously involved, as well as the ovary. When, however, the tube is healthy or shows but a slight thickening of its walls, or a congested condition, with permeable lumen and orifices is present, he gives the preference to partial resection of the ovary or ignipuncture of the cystic follicles. It is the author's practice, in the case of a large cyst, to resect as completely as possible the diseased tissue, and suture the wound with catgut. When, however, numerous small cysts are present, he has obtained his best results from multiple ignipuncture; care being exercised to allow no smallest cyst to escape cauterization, lest it should increase in size and give rise to a return of the distressing symptoms. The immediate relief obtained by such conservative operations has been, in Boursier's experience, invariable; though in a certain number of cases, there was a temporary return of pain as the menstrual period was approaching and in nervous subjects, a continuance of pain was not uncommon. A complete cure is recorded in 30 per cent. of the author's cases and pregnancy occurred in 2 out of the 23 who were kept under observation.

**Uterine Myomata and Sterility.**—The statistical evidence presented by numerous authors is so contradictory that no definite conclusions can be drawn as to the direct influence of uterine myomata on sterility. Some further figures are presented by L. Austerlitz (Prag. med. Woch., June 11, 1903), who brings forward the clinical material of the gynecological clinic at Prague seen during a period of nine years and including 5,217 cases. Of these 339 or 6.5 per cent. were afflicted with uterine myomata, and among 302 of the latter class, who were married, 80 never carried a child to term and 67 never conceived. The remainder were fertile. Considering a primary sterility as a condition in which conception had not occurred during the first five years of married life, or where five years had elapsed after child-bearing without any conception following, it was found that this occurred in 151 cases, or 4.17 per cent., which presented no evidences of myomatous disease, and in 61 cases, or 20.23 per cent., afflicted with myomata. Secondary sterility in the former class was found in 13.68 per cent., and in the latter in 21.85 per cent. This evidence shows that there must be some relation existing between myomata and sterility. Fertility seemed least affected by the submucous myoma, especially of the pedunculated variety, and successively more by the subserous, interstitial and the mixed forms. Among the unmarried cases conception also seems to have been markedly influenced by the presence of myomata, for in the latter case it occurred in 18 per cent., while among the non-afflicted unmarried women, conception took place in 56 per cent.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Agglutination of the Bacillus Subtilis.**—The number of spore-bearing micro-organisms for which agglutination has been determined is comparatively small. S. S Kneas and J. Sailer (Univ. Penn. Med. Bull., June, 1903) have found that the *Bacillus subtilis* gives a typical reaction of agglutination with the blood serum of rabbits into which it has been injected, in dilutions as high as $^1/_{2500}$. Owing to its size and motility, it is an excellent subject for the demonstration of this reaction. Although it has generally been considered one of the most perfect types of a non-pathogenic micro-organism, later investigations have shown that under certain circumstances it may become pathogenic, causing death in the lower animals and a destructive inflammation in human beings. A number of such cases have been reported but nothing definite has been formulated.

**Chemical Pathology of Acromegaly.**—The chemical abnormalities that occur in this disease have been but little studied. Some recent studies on this subject have been made by D. L. Edsall and C. W. Miller (Univ. Penn. Med. Bull., June, 1903) on one case which exhibited striking progress and presented no signs of diabetes, and were controlled by another in which the disease was at a standstill. Careful measurements were taken and the food, consisting of milk, meat, rice, bread and butter, analyzed for the quantity of $P_2O_5$, CaO, and N. Analyses of urine and feces were then made. The figures in general demonstrate a striking retention of phosphorus and nitrogen, and a less marked retention of calcium, a condition of affairs that is somewhat remarkable when we consider that in this disease the skeleton shows such notable changes. The excessive nitrogen retention gave expression in the abnormal growth of the soft tissues, a common feature of this disease. The very large retention of phosphorus can only be explained by considering that it is used in constructing tissue that is especially rich in phosphorus, as the calcium retention was relatively small. As these cases are usually imbecile, it may be assumed that the overgrowth is in the nervous tissues. Under normal circumstances the amount of calcium in the daily feces is eight or ten times the amount in the daily urine. In this case, however, the amount in the urine nearly equaled that in the feces. This is a condition frequently met with in diabetes mellitus, when acid intoxication is present, and has also been produced by a strict proteid and fat diet. No definite conclusions could be reached from the experiments made to explain this fact, but it seems that there is some abnormality of metabolism that causes a solution of calcium from the bones at the same time that there is in other parts of the bone an abnormal deposition of bone salts. This does not appear to be the result of general acid intoxication, but is probably due to the formation of some acid that combines with calcium with especial readiness. Some of the calcium is apparently carried off in solution, another part may be simply redeposited and leads to the abnormal growth of bone. Of this, however, we have no definite knowledge. These observations seem to emphasize the view that there is in acromegaly a growth of abnormal bone rather than a mere abnormal growth of bone, and that there are every marked abnormalities in the soft tissues, as well as in the bones. Further studies may demonstrate that the alterations in the bones are the result of metabolic abnormalities rather than of a mere tendency to distorted overgrowth.

**Proteinochrom, a New Color Reaction.**—Some years ago a substance of undetermined chemical composition was discovered as one of the end products of albuminoid disintegration, which reacted with chlorine or bromine to form a violet-red pigment body—proteinochrom. It was found to occur as a result of fermentation in pancreatic digestion, and as the result of bacterial action in the decay of albuminoid substances. Some further clinical and bacteriological investigations have lately been conducted by P. Erdmann and H. Winternitz (Münch. med. Woch., June 9, 1903). Attempts to demonstrate the presence of proteinochrom

during gastric digestion after test meals in perfectly normal individuals, were unsuccessful, as were also those in pathological cases of a non-malignant type, such as chronic gastritis, anacidity, sub- and hyperacidity. In cases of malignant disease, the reaction could only be demonstrated when there was present a retention of the gastric contents, due to stenosis. When the stomach was washed out before the test meal was given, no reaction was found. As a differential diagnostic sign, the test is therefore only of value in advanced cases. The reaction was also demonstrated in the diarrheal stools accompanying tuberculosis, chronic catarrhal enteritis and typhoid. In normal feces the reaction was not found. As the proteinochrom was believed to be a product of bacterial metabolism, particular attention was given to its appearance during the growth of various bacteria on suitable media. It may be compared with indol, which is a product of the same sort, although of somewhat different origin. The tests were made on solutions and bouillons made with peptone. Large numbers of bacterial species were studied, and it was found that proteinochrom was formed by the majority, although the appearance of the reaction varied from one to ten days. If the appearance was delayed longer than ten days, the test was considered negative. Comparing the results with the tests for indol, it was seen that certain bacteria formed indol but no proteinochrom, whereas others formed both, but with a marked difference in time of appearance. The diagnostic value of the reaction depends on the information which it affords regarding the biochemic activity of the bacteria, in other words, to what stage the bacterial disintegration of the albuminoids has proceeded, the appearance of the proteinochrom reaction indicating that it has advanced to the formation of leucin and tyrosin. In differentiating a typhoid from a *Bacillus coli* infection, it was satisfactorily demonstrated that cultures of the latter showed no proteinochrom reaction, while the presence of indol could be demonstrated on the second day. In contradistinction to this, the cultures of typhoid bacilli showed the proteinochrom reaction from the second day on, whereas the indol had not appeared by the fourteenth day. This seems to point favorably to a new color reaction for the typhoid bacillus, which may aid in differentiating it from the *Bacillus coli communis* in doubtful cases.

## GENITO-URINARY AND SKIN DISEASES.

**Myositis Syphilitica.**—In a study on Myositis Syphilitica, J. A. FORDYCE (Jour. of Cut. Dis., April, 1903) says that the involvement of the muscular system by syphilis is of relatively rare occurrence. Matzenaur, in Neumann's clinic, has observed, in the early period of the disease, one or two cases among seven thousand patients with syphilis. The early so-called myalgias may be due to hyperemia with slight exudation in the connective tissue of these organs or to irritation of the peripheral nerve by the disseminated poison of the disease. They have, as a rule, little clinical significance, as they usually rapidly disappear. The majority of textbooks on syphilis speak only of the diffuse interstitial myositis of the early period and the circumscribed gummatous tumors of the late stage. It is not always possible, however, to assign the cases seen in clinics to these two groups. In malignant precocious syphilis, gummata, usually in several muscles, have been observed in the early period of the disease. Matzenaur has seen multiple diffuse myositis and gummata in the same patient and the same conditions in the late stages of the affection. He has also called attention to the occurrence of muscle abscess following a diffuse myositis four and seven months after infection. A single muscle gumma in late syphilis can readily be mistaken for a sarcoma or other muscle tumors or infiltrations. Hartley has recently emphasized the importance of syphilis from the surgeon's standpoint, and has called attention to numerous errors in diagnosis in these and other specific conditions. The possibilities of syphilis are perhaps not so keenly appreciated by the general surgeon as by the syphiligrapher, and for this reason the observations of the one should supplement those of the other. Another type of myositis, presumably syphilitic, has been described by Herrick, in which a syphilitic patient suddenly developed painful swellings in the supinator longus and in the calf muscles. Examination of pieces of the involved tissue showed a diffuse inflammation with hemorrhages. He failed to find either vegetable or animal parasites, and attributed the condition to a specific infection ten years before the present trouble began. The author's critical comparison of his own case with the disease known as polymyositis acuta leaves doubt as to its true nature. The disappearance of the muscle swelling under such doubtful antisyphilitic treatment as iodine and iodide of potassium ointment scarcely lend weight to such a diagnosis. The histological investigations of Matzenaur show that the initial changes in the interstitial myositis and the gummatous variety are the same. In early syphilis the inflammatory process tending rather to diffuse changes, while in late syphilis more sharply circumscribed infiltrations result. The blood-vessels of the interfibrillary connective tissue are first implicated; the muscle-substance being secondarily involved. The preservation of the functional integrity of the muscle can only be secured by early recognition of the nature of the disease and a prompt recourse to specific remedies. The results of the affection are seen in the sclerotic changes which take place in the tongue as a result of chronic interstitial myositis in this organ.

**Massage of the Prostate and Albuminuria.**—The universal employment of massage in the treatment of gonorrheal prostatitis lends interest to the following observations of C. KRUGER (Münch. med. Woch., June 9, 1903). Two patients of nervous disposition, but otherwise normal, presented a chronic prostatitis of a gonorrheal origin, for which massage was instituted. During a period of five weeks albumin was constantly present in the urine while the massage was continued. A nephritis could not be demonstrated and sources of albumin from the contents of the bladder could also be excluded. In one patient a transitory albuminuria appeared on severe exertion at other times, but was not evident during the period of treatment. Tests were also made after various exercises in both patients, but resulted negatively. The author advises careful watching of the urine for the appearance of albumin in these cases and if combined with the presence of renal epithelium and casts, the massage should be stopped, and guardedly continued in the other cases. The author advances several hypotheses for the appearance of this condition, the principal idea being that the diseased prostate secretes substances, which have an irritating effect on the kidneys during the process of excretion, after they have been forced into the circulation by the massage.

**Diagnosis of Leprosy.**—An interesting account of the routine method of examining cases of leprosy in Hawaii is given by J. T. MCDONALD (Jour. Am. Med. Ass'n, June 6, 1903), who also draws particular attention to the general prevalence of the disease and the liability of its being undiscovered. He details the observations made on 150 cases. As a means of diagnosis the microscope stands in first importance, a minute strip of tissue being teased out and stained with Ziehl's carbol fuchsin in the same manner as for tuberculous sputum. Of clinical symptoms, maculæ, chiefly leucodermic spots are found in 89 per cent. of all cases. The lepra nodule

found in 74 per cent. is the chief distinguishing lesion of skin leprosy. Thinning or complete loss of eyebrows and eyelashes is present in 63 per cent. Atrophic changes in hands and forearms with retraction and contraction of fingers and enlarged ulnar nerve in 32 per cent., is a leading feature of nerve leprosy. The plantar ulcer was found in 26 per cent., absorption of phalanges in 16 per cent., facial paralysis in 11 per cent. The entire body should be carefully tested for anesthetic areas.

**Treatment of Nevus by Hot Water.**—The coagulating power of heat has been turned to good account by its use in the treatment of nevoid growths. F. Griffith (N. Y. Med. Jour., May 2, 1903) reports a case of nevus of the scalp and nose in a child seven months old where this mode of treatment proved very efficacious. Injections were made by means of a sterile hypodermic syringe and needle with the sterile water at a temperature of from 180° to 200° F. One fluid dram was injected without the aid of anesthetics and reaction was manifested by distention of the mark till it became a tense, blanched, cystic tumor. Injections were continued every three or four days for a period of three weeks when shrinkage and a flattening of the mark at a level of the surrounding surface had taken place.

## EYE, EAR, NOSE AND THROAT.

**Treatment of Purulent Conjunctivitis.**—The first step in the treatment of every case of purulent conjunctivitis should be the microscopical examination of the pus to determine the variety of micro-organism present. If the examination cannot be made at once it is usually best not to delay treatment to await the results. E. S. Thomas (Med. Rec., May 30, 1903) doubts whether the mild cases of conjunctivitis are ever gonorrheal in origin, so virulent is the usual condition produced by this germ and it is a fact that in the mild cases the gonococcus is not found. When the case is seen early a two-per-cent. solution of silver nitrate should be at once thoroughly applied to the whole conjunctival sac and an applicator with cotton should be carried entirely through the cul-de-sac under the upper lid. This latter procedure cannot be employed in children, but a thorough cleansing can usually be done. If the case is seen later and is very severe, a daily application of a three- or four-per-cent. silver solution may be indicated. With these stronger solutions it is best to neutralize with salt solution and also lay a pledget of cotton soaked in salt solution upon the cornea while making the application. Daily applications of silver are to be supplemented by irrigations with boracic acid solution, frequent enough to keep all secretions washed out. Cold applications prevent too great a reaction to the silver. Protargol is sometimes indicated when silver proves too irritating, as evidenced by increased discharge of serum and a tendency to bleeding. Protargol should not be used in stronger solutions than six per cent. Argyrol, 25 per cent., is actively germicidal and non-irritating and is a very valuable application if the astringent action of silver is not required. Protargol and argyrol are especially applicable to the cornea, as no staining may be feared from their use.

**Blepharitis Marginalis.**—Intractable cases of this disease are frequently met with and the routine treatment of text-books is found very unsatisfactory. D. S. Reynolds (N. Y. Med. Jour., June 6, 1903) has departed somewhat from the customary use of ointments in some of these cases and has obtained excellent results. One of the commonest forms of blepharitis marginalis seen in persons of every rank and station in life and of all ages, is that in which there is slight thickening of the borders of the lids. The anterior margins are dry and red, and the lash on close inspection is observed to be thin, while the cuticle between the hairs is covered with minute scales of desquamating epidermis. Many of these cases disappear entirely under correction of errors of refraction, of intestinal constipation and various conditions of malnutrition. Oftentimes, however, a complete cure seems almost impossible and recurrences are frequent. There is a fungus undoubtedly present in the hair follicles of such cases, and it is believed that these may be best eradicated by the periodical application of pure carbolic acid. The acid is prepared by adding about ten minims of alcohol to a dram of crystallized carbolic acid and agitating sufficiently to dissolve the acid. The point of a needle is dipped into this fluid and while the lid is firmly held with one hand, the detachable scales between the hairs are scraped off and the application of the acid made as direct and complete as possible to all the hair follicles of the margin of the lid. By repeatedly dipping the needle into the acid and scraping the skin, taking care that none shall run over the free border, the application can be made so thorough as to whiten all that portion of the skin containing the lash. The smarting which results should last only a few minutes. About the fifth day a crust of epidermis may be removed and a yellow oxide of mercury ointment applied. The carbolic treatment should be repeated in about ten days and in about three months, in most cases, a luxurious growth of lash has come in and with it an entire disappearance of all signs of blepharitis. In the more advanced cases which present an excoriated, glazed, rounded appearance of the torsal margin with no sign of lash or even in those instances where the removal of an abundant accumulation of inspissated serum discloses an ulcerated condition of the lids the use of the phenol is very beneficial. In the latter condition the ulcer should be thoroughly cleansed and dried and then the phenol carefully applied to its base. Striking results are thus frequently obtained.

## THERAPEUTICS.

**Vassale's Paraganglina in Gastro-intestinal Atony.**—The effect of this remedy—an extract of the suprarenal capsule of the ox—upon gastro-intestinal atony has been studied, in a series of cases, by U. Baccarani and A. Plessi (Gazz. Osped., June 7, 1903). The known effect of the suprarenal's active principle (which has been shown to reside in the medulla) upon unstriped muscular fibers, inducing their more forceful contraction and maintaining their tone, has, in the author's cases of gastro-intestinal atony, exerted a uniformly favorable influence. In gastric atony, 40 to 60 drops, divided in 5 to 8 daily doses, gave speedy relief and in the majority of cases, the cure was permanent, after suspension of treatment. In a certain number of cases, the remedy, when given by mouth, failed to influence intestinal atony; though there was immediate response to its effect when injected into the rectum. From this the authors conclude that atony of the large intestine was responsible for constipation in the latter class of cases and that atony of the small intestine was indicated when a favorable effect followed its administration per os.

**Antnrasol, a New Tar Preparation.**—The objectionable features of the ordinary tar preparations have led to the attempt to produce a substance free from the pitch and coloring matters, and one which, being in a more fluid form, would be less liable to become thick and harden. A. Sack and H. Vieth (Münch. med. Woch., May 5, 1903) have succeeded in producing a purified tar, which is fluid, of a light yellow color, and of the consistency of olive oil, but possesses the characteristic odor of tar. On account of its thin consistency it can be readily applied with a brush. It penetrates the skin very readily and leaves no residue.

# THE MEDICAL NEWS.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## RADIO-ACTIVITY AND ITS POSSIBILITIES IN THERAPEUTICS.

RENEWED attention has recently been called to the substances that produce special spontaneous radiations which affect photographic plates and various sense organs of the human body and are physically recognizable in a number of curious ways. Professor Marckwald, of Berlin, made a series of demonstrations at the sessions of the International Chemical Congress held in Berlin during June. The metal experimented with was polonium, which so far has been but very little known and whose full powers were only more or less suspected. There is no doubt now that this new metal has the power of communicating the radio-active energy which it possesses to a number of other substances and that in this respect it must be compared with, if indeed its qualities do not exceed, the similar properties of radium. Now that physical therapeutic measures, hydrotherapy, massage, and vibratory stimulation of various kinds are coming to have due recognition as important remedial agents there is hope that these new metals may also prove of special service in the treatment of affections likely to be influenced by nervous stimulation or trophic alterations of any kind.

It is now some years ago since Professor Javal, the distinguished French ophthalmologist announced to the French Ophthalmological Society, that the X-rays could be made to produce certain effects upon the optic nerve of patients whose ocular media were disturbed. A short time after he made the additional announcement that uranium and the Becquerel rays, and, especially, radium with its wonderfully active qualities, might be of service not only in diagnosis, but to a certain extent in supplying the stimulus of the optic nerve that is ordinarily produced by light. The usually accepted discoverer of radium, M. Curie (though it is now definitely announced that he owes his temptation to study these substances to the initiative of Madame Curie, who had already made definite progress and more than suspected the existence of radium before her husband entered the field), pointed out at the beginning of his investigations on radium that the metal had a very definite action on superficial cutaneous nerves. He found that if a small glass vial containing even a minute quantity of a more or less pure radium salt were carried in the pockets for some hours the skin beneath the pocket became reddened, later it lost its superficial covering with the production of an ulcer rather difficult to heal.

This effect would seem to be manifestly a result of interference with the trophic nerve fibers leading to the particular skin area. The effect is not produced immediately but, as in the case of the X-rays, may be delayed for many hours or even days. The ulcer produced shows practically no tendency to heal for a considerable period, so that evidently the vital resistance of the part somehow dependent on its connection with the central nervous system is very much lowered. In recent times M. Curie has expressed the opinion that if a considerable quantity of radium in its pure state could be obtained, say, for instance, a kilogram (2⅕ pounds) that he would not care to enter the room in which it was placed, since there would be danger of lasting injury to the optic nerve and to the skin surface all over the body.

It seems clear that agents as powerful as these substances seem to be may well prove to have an important place in modern therapeutics. It is only within this last year or two that it became clear that for some forms of malignant disease the X-rays produce wonderful and as yet inexplicable effects that resemble, more than any other method of treatment ever introduced, nature's curative process in certain very fortunate cases of malignant disease in which the growth disappears spon-

taneously. Just what the effect is due to cannot as yet be determined. It would seem, however, that the growth of a neoplasm, even of a malignant type, depends on the trophic influences transmitted to it from the central nervous system. While the overgrowth of certain cells is a true insurrection among the citizen cells of the republic of the body, these depend for their possibilities of overgrowth on the ordinary metabolic processes of the system which are so much under the domination of trophic nerve centers. If nerves can be interfered with then by means of the paralyzing action of forms of radiant energy such as are now familiar in the X-rays and the radiant metals, it is not impossible that a very perfect method of cure for malignant disease may be at hand.

Up to the present time the price of these metals makes medical experimentation practically impossible. Radium, by those familiar with the conditions, is said to be worth about $2,000,000 a pound. It is not improbable, however, that other sources of the metals will be found than the one collection of mineral material in which, so far, they have been demonstrated to exist. Pitchblende is common enough and while only the one variety of pitchblende that is found in the Joachimsthal in Austria has so far proved to contain the precious radiant metallic combinations, it is not unlikely that corresponding material may be found among the rich and varied mineral deposits in our own country. As the material from which they are obtained is originally a waste product the value of the metals may be very much reduced by such a discovery.

Methods of preparation, which at present are long and complicated, constitute the real expense and these have been very much simplified in the last year, according to an announcement from Madame Curie herself, and there seems no doubt that further simplifications with great reduction in the price of these substances will occur in the near future.

Meantime we shall wait with not entirely hopeless anxiety to hear the first results from the therapeutic use of these metals. Professor Marckwald's demonstrations at Berlin make it clear that polonium is capable of communicating its radiant energy to many other substances in a very marked way. It is this quality that most of all might be expected to be of use in therapeutics. In his demonstrations Professor Marckwald used only about one-sixth of a grain of polonium. This indicates the wonderful latent energy that is contained in the new metal and shows that the time will not have to be waited for when large quantities of it are at hand for experimental purposes before the metal can be used in practical medicine.

---

### THE MOSQUITO'S DEATH KNELL.

The old saw that "Big fleas have little fleas to bite them; and little fleas have lesser fleas, and so *ad infinitum*," is applied very ingeniously by Dr. Charles Warner Stiles—whom we might designate as the great American germ discoverer—to the extermination of the mosquito. In addition to serving as intermediary host for the parasite of malaria, the mosquito, it seems, entertains a little on his own account. He has a plague of a guest, named *Agamomermis culicis*, a parasite that kills millions of mosquitoes each year. If it is a "bad year for mosquitoes," the assumption is that it is a good year for *Agamomermis culicis*. This parasite has its habitat in the abdomen of the mosquito. Infection takes place in the larval or pupal stages of the mosquito. The infected mosquitoes are sluggish and short-lived, and the females do not breed.

Now, if the parasite can be cultivated and let loose upon the unborn mosquito, the theory is that he will be exterminated, and the place thereof shall know him no more. The only difficulty is how to do it. Possibly one might do cultures of this fatal parasite up in portable form like a fire extinguisher, with a small family size for cottage use, and a larger size for hotels. There could even be a handkerchief culture, something like a nitrite of amyl drop, that could be crushed in a handkerchief, letting the germs loose while walking through the meadows to one's suburban home.

The only satisfaction, however, that one could have on such occasions would be the purely altruistic one of infecting the young of the mosquitoes that were biting at the time, so there should be fewer to bite one's neighbor when he walked that way. If people were only more apt to be altruistic when they were being bitten by mosquitoes this scheme of throwing their parasites at them might work very well, and whole communities could combine and subscribe for the cultures.

Dr. Stiles admits that there is a little practical difficulty in distributing the parasite; but the government, we are led to believe, thinks it is the greatest thing out. And so it undoubtedly will be when Dr. Stiles has discovered some rapid and inexpensive way of breeding *Agamomermis culicis* in all the marshes where mosquitoes live.

## HYGIENE IN THE PUBLIC SCHOOLS.

EACH year, just after the close of the schools, the Regents of the University of the State of New York invite all those formally connected with educational institutions of various kinds in New York State and all others who are interested in our educational system to a conference held at Albany and known as University Convocation.

We are very glad to find that one of the discussions at the convocation this year had for its subject the important question of the teaching of hygiene in our public schools.

There is no doubt in the minds of those who have looked into the matter with any care that the present system of teaching hygiene to our public school children is not only inadequate to the purpose of giving a reasonable idea of an important practical, applied science, but also some of the prominent features of the teaching of what is supposed to be hygiene are not in accord with the opinions of those who in medicine and physiology as well as bacteriology and sanitary science are most favorably situated to know what the trend of scientific thought is at the present moment.

The discussion at Albany on June 30 was opened this year by Dr. Helen Putnam, of Providence, R. I., who suggested the necessity in the high schools of large cities, at least, of a special department of hygiene, to be presided over by some one who has made special studies in this branch. Her paper worked out in detail the arrangement and management of this department. There is no doubt that the recent progress in the science of hygiene not only amply justifies this idea, but it seems evident that no other satisfactory method of teaching this important subject can well be devised.

After all the most fundamental element in the establishment of a special department of hygiene must be the assurance that this department shall keep thoroughly abreast of the times, and as hygiene is above all an advancing subject, only those who are well grounded in all its principles should be permitted to instruct in this important branch. The development of our public school teaching of hygiene must come, and it is along these lines of specialism so accordant with the specialistic tendencies of our time that reorganization should be directed.

As was brought out in the discussion of Dr. Putnam's paper, the importance and the interest of hygiene as a subject for study among school children can scarcely be exaggerated.

Sanitarians have been making history in recent years that is much more important for the happiness and the evolution of the race than anything that the military men have ever succeeded in doing. None of our military operations during the Spanish-American War compare at all in importance or even in the effect they will produce to what has been accomplished by the army medical department for the sanitation of the West Indies during our few years of occupation of Cuba. There has not been a single case of yellow fever in Havana for nearly two years, though that disease was endemic there for probably two hundred years and there has been no case of smallpox for over two years, although that disease constituted one of the most serious occasional factors in the death-rate in the Island. The study of the fevers and peculiar anemias of Porto Rico has given important hints for the elucidation of anemic conditions not necessarily connected with malaria in tropical countries all over the world. Surely American children should know something of what is thus being accomplished by their fellow countrymen. There will be no lack of interest in the matter if it is only properly presented.

Sanitation has accomplished great wonders in other parts of the world as well as in the tropics. There are many thousands of people saved from death every year as the result of the enforcement of sanitary regulations in large cities, who would have been brought to an untimely grave if the death-rate of even ten years ago continued to prevail during the last two or three years. The head of the Board of Health, of Chicago, announced, as the hot weather came on, that there would be many thousand fewer little graves in the cemeteries of Chicago this year than were necessary even five years ago, though the city has increased in population not a little during the last five years, because the factors on which infant mortality depend are better understood and better methods for its diminution are in vogue.

The progressive president of our greatest university in this country, who is accustomed to interest himself in all matters of significance for education announced some time ago that our public school system was not fulfilling its purpose, since our people, all over the country, were still as ready as ever to be fooled by the fake advertiser of every kind—the palmist, the get-rich-quick man, the patent medicine vender, and all the others of that ilk. Surely the reorganization of the teaching of hygiene on a proper scientific basis in our public schools would do something to get us rid of the present influence which the

quack medicine fakir continues to wield over so many of the supposedly intelligent population of this country.

At the present time public school text-books call attention to the evils of alcohol with unstinted zeal though no mention is made of the fact that practically all of the most advertised patent medicines, the best known and the most used, all the wonderful tonics are really nothing more than alcohol made properly bitter by the addition of certain pharmaceutical materials which serve to give them a definite medicinal taste.

In the improvement of public school systems now become the favorite study of our best educators surely this subject of the proper teaching of hygiene should receive its due share of attention. There are those closely in touch with the public school system who feel that there are many things now forced upon the occupation of children that are scarcely more than show subjects. The satire upon the high school graduate of a year or two ago by one of our best-known comic weeklies that he and she carried with them out of school the burden of many volumes of useless information is not without its share of truth. We are not of those who believe only in practical education, but surely the matter of individual and community health is one of those important practical subjects that every young person should be given the basic principles that underlie its preservation. We shall look for some true progress along this line, now that educators seem to have taken the matter up seriously.

## A NEW DEPARTURE.

In these days when a gullible public prescribes for itself from the patent medicines on the frieze of the trolley-cars, or takes the profitable substitution that the druggist passes over the counter, it is no wonder that physicians feel a bit out of sympathy with the venders of drugs, and make unfavorable comparisons between the commercialism of the men who supply medicines and the science of the medical profession that prescribes them.

But we should never forget that were it not for the great manufacturers and importers of drugs we might still cull our own herbs, and use our own mortars and pestles. As an indication of the aid that such houses may be to physicians, we call attention to the colored plates of pathogenic organisms that have been prepared for the profession by the house of M. J. Breitenbach Co., the importers of Gude's Pepto-Mangan. By their permission we have inserted a few of the set of sixty in our advertising pages.

No text-book and no one work on pathogenic bacteria contains such a number of excellent diagnostic illustrations, nor such beautiful examples of lithographic art as these.

Many physicians are too far from libraries and laboratories to be able to put into practice the training of their college days. They need just such a set of reference plates to be able to make microscopical examinations. The recognition of this need and the care that has been taken to fill it shows a spirit of enterprise in this firm that we wish might serve as an example to others. For, if, instead of advertising to the public the manufacturers of drugs would make such valuable contributions to science as lies in their power there might be more sympathy between them and physicians.

The full set of sixty cuts has been prepared to send to any physician who writes for them, from the firm of M. J. Breitenbach Co., New York.

## ECHOES AND NEWS.

### NEW YORK.

**A Hospital for Consumptive Poor.**—The project of a tuberculosis hospital, to be founded by the City of New York for the treatment of incipient cases, on high ground back of the Hudson in Orange or Rockland County, appears likely of realization. The plan and scope of the scheme have been discussed in administration circles for several months and they may be laid before the Board of Estimate and Apportionment or come before the Board of Aldermen during the present month.

Mayor Low has all the details of the needs and capacity of the proposed institution from Commissioner Lederle of the Health Department, Commissioner Homer Folks of the Charities Department, and many scientific men. It was stated semi-officially that the hospital—land and buildings—would cost from $350,000 to $500,000, and would be under the control of the Board of Trustees of Bellevue Hospital.

**Tuberculosis Fakirs.**—The following from the *Herald* is worthy of preservation in medical literature as illustrating the methods of many similar institutions:

When the prosecution is ready to act in suppressing the many so-called "Koch" cure establishments purporting to be affiliated with Professor Robert Koch, the distinguished German tuberculosis expert, but which he has expressly repudiated no less than thirty times in letters sent to representative men in America, a mass of testimony will be ready. In addition to the data already prepared for the counsel of the County Medical Society, which has been investigating these so-called "Koch" lung cure concerns for nearly two years, it was learned last week that a former nurse at the West Twenty-second street establishment, who has also had experience at several other branches, has volunteered to tell some astonishing particulars about the manner of conducting business in these "consumption parlors."

This woman is now employed at a hospital in this city. She first entered the employ of the so-called Koch Lung Cure Company in Philadelphia, where a sort of training school for nurses is maintained by the parent office. Then she went to the Rochester establishment. Here is what she said when asked about her experience there:

"I had charge of the business department there. I received the patients when they first came to the office; I placed the advertisements, prepared the tuberculin and was the general supervisor of the office. I kept the books and banked the money most of the time."

"What was the treatment that was adopted in that office during the time you were there in charge?" she was asked.

"We got the tuberculin from the Koch Lung Cure office, No. 150 Nassau street, in little bottles containing about an ounce. This was used with six ounces of albolene. The albolene was colored for the consumption cases and bronchitis and the tuberculin that was used for asthma was plain white. We used alkanet root for coloring."

"How many patients were cured at that place?"

"None."

"How many ever gave testimonials as to being benefited or cured?"

"I think we got three who said they had been benefited, but never any that were cured."

This nurse was then asked about a letter which she said she had written by the direction of Wallace Cleveland Clark, M.D., the head of this particular so-called Koch Lung Cure Company, running as follows:

"We are interested in your case and want you to get well. We are glad to say that, through the generosity of a wealthy lady, whom we have cured, certain money has been placed at our disposal to assist deserving cases to take our treatment. Call soon, as we are making this same offer to others, and it will be a case of first come first served. Respectfully, K. L. C."

"What does 'K. L. C.' stand for?"

"The Koch Lung Cure."

"Was that the way Dr. Clark directed you to write the letter?"

"Yes."

"Do you know whether or not a generous lady, or any lady, was cured by the Koch lung cure and had deposited a sum of money for the purpose of benefiting other sufferers, as stated in this letter?"

"I can say positively that I know no wealthy lady was cured in Rochester and that there was never a dollar deposited for any such charitable purpose."

"What would you say, basing your statement upon your experience with the company while you were in its service, and from your observation, is the main object of the company in its advertisements?"

"To get money, to get rich, and absolutely nothing else."

"From what you know of your own knowledge concerning the company's mode of treatment and sale of medicine and general advertisements, would you state whether or not there is any virtue in its treatment and if it does humanity good or relieves the sick and suffering from consumption?"

"I would not take it myself."

"What do you say generally, based upon your experience?"

"I do not believe that it is any good."

Besides the testimony of this nurse, who has been in consultation during the last few days with Mr. Champe S. Andrews, the counsel for the New York County Medical Society, the method of the spurious "Koch" companies in obtaining testimonials has been investigated.

Here are extracts from a letter sent to a woman in Washington, D. C., signed W. C. Clark, the president of the concern:

"DEAR MADAM: You are probably aware of the fact that your testimonial has been inserted in the papers, and we realize that you are put to considerable trouble in answering letters and inquiries that come to you about your cure.

Should any one desire to have you call and see them at their home and you can spare the time, we would be very much pleased to have you do it. Of course, a dollar would be a very small fee for such a visit and we would be very glad to pay it. * * *

Kindly instruct us to answer them (the letters) for you and we will simply state that your case was cured, as stated in the testimonial. I believe that is all that is necessary. Hoping that you will take this in the spirit in which it is sent and will allow us to at least give you the amount that you would otherwise earn for the same amount of time, given, I mean, twenty cents per letter and twenty cents for each inquiry, I remain, very sincerely yours, W. C. CLARK."

This adroit scheme to obtain many alleged testimonials is said to have had an odd sequel, which may be brought out in the crusade of the County Medical Society against these impersonators of the German tuberculosis investigator.

## PHILADELPHIA.

**Tetanus Follows Toy Pistol Wounds.**—Seven deaths from tetanus have occurred during the three days preceding the writing of this letter. Of these five occurred in children, the wound in each case being caused by toy pistol. As usual the manufacturers and retailers of the fire-arms are blamed by the coroner, and the matter is allowed to drop. Efforts are being made in some of the laboratories of the city to determine if tetanus bacilli are lodged in any part of the ammunition used or if they are introduced into the wound from other sources. The results thus far have been negative.

**Crusade Against Smallpox Begun.**—Vigorous efforts are being made to prevent the spread of smallpox which has been increasing during the past two weeks. House to house vaccination is being carried out in the Twenty-eighth Ward which contains the greatest number of cases. The streets in those localities are to be flushed each day by the firemen. The Board of Health has notified the proprietors of stores that their places of business will be closed for fumigation whenever a case of smallpox develops. As a result the proprietors of two large department stores have notified their employes that all who have not been vaccinated within five years must submit to vaccination or be dismissed. There recently died at the Municipal Hospital a druggist who had been vaccinated unsuccessfully twenty-four times.

## CHICAGO.

**Appointment of Dr. Wm. L. Ballenger.**—Dr. William L. Ballenger has been elected to the Chair of Otology, Rhinology and Laryngology, made vacant by the resignation of Dr. Moreau R. Brown.

**Appointment of Dr. Frank Allport.**—Dr. Frank Allport has been elected Clinical Professor of Ophthalmology in the Northwestern University Medical School.

**Incorporation of Englewood Hospital.**—A new corporation has been organized, known as the Englewood Hospital and Training School. This will succeed the Englewood Union Hospital, which will surrender its charter. The new institution is not for pecuniary

profit. The plan contemplates the purchase of land for $20,000, on which will be erected a hospital building to cost $80,000, and to accommodate 148 patients, and this building will be equipped at a cost of $20,000.

**Effect of Hot Weather.**—Owing to the sudden onset of hot weather during the week ended July 4, 563 deaths were recorded, an increase of 109 over the preceding week, or about 24 per cent.

**Issuance of Permits to Hospitals.**—The Corporation Counsel has advised Health Commissioner Reynolds to issue licenses to general hospitals, even though neighboring property owners should object, serve written notice on the Mayor and Commissioner, and threaten suit for damages.

**Commencement Exercises of Jenner Medical College.**—Jenner Medical College held its graduating exercises June 30. Dr. G. Frank Lydston delivered the doctorate address on "The Young Man's Way to Success."

**Graduation Exercises of Harvey Medical College.**—This college graduated a class of 20 on June 27. Dr. Frederick D. Marshall presided, and Carl Svante Nicanor Hallberg, Ph.G., on whom was conferred the honorary degree of Doctor of Medicine, delivered an address.

**Northwestern Alumni Week.**—The exercises of alumni week at Northwestern University Medical School were attended by about 200 former graduates of the institution. Special clinics were held. At the banquet, Dr. Archibald Church acted as toastmaster, President James of the University welcomed the guests, and Hon. A. N. Waterman, Rev. I. A. White and Frederick Greeley spoke.

**Death of Dr. De Laskie Miller.**—Dr. De Laskie Miller died July 9, in this city. He was one of the oldest of Chicago's physicians, and had been prominent in the profession for many years. Dr. Miller was eighty-six years old.

## CANADA.

**Providing for the Ontario Epileptic.**—Woodstock, Ont., has been selected as the site for the buildings which the Ontario Government will erect for the care of epileptics in this Province. Accommodation will be provided for 100 patients, in all the best and most modern style. The institution will be extended as necessity demands.

**The Universities in Toronto Federating.**—It almost seems to be an assured fact that the 200 odd students of Trinity Medical College will be associated with the 400 medical students of Toronto University in the new medical building which has just been completed by the latter. The two medical faculties have already arranged the terms of union, and it but remains for the corporation of Trinity University to agree to federation. The scheme for federation between the two Universities has been laid before the Government, and it has met with their approval. Amalgamation has been most talked of between these two medical colleges during the past six months, and there are many who hope for the cause of medical education in Ontario, that the medical schools will open as a united body at the beginning of the next session.

**The Practice of Christian Science Gets a Setback.**—In November, 1901, at Toronto, a citizen was convicted of manslaughter on the charge that he had failed to provide medical attendance for his son, a boy aged sixteen years, who died from diphtheria. After the conviction had been secured at the Assize Court the matter was taken to the Court of Appeal, where the judgment of the lower court was confirmed. According to this decision it was found that there was sufficient evidence to warrant the verdict. This court also thought that the learned judge properly charged the jury that the word "necessaries" as used in the criminal code, includes medicine and medical treatment.

**Maritime Medical Association.**—It is now twelve years since this Association was organized at St. John, N. B. It will hold its annual meeting this year on July 22 and 23, in that city. One of the distinguished visitors who will attend and contribute a paper will be Dr. Maurice H. Richardson, of Boston, U. S. A. A paper on gynecology will be read by Dr. E. W. Cushing, also of Boston. Dr. G. E. Armstrong, of Montreal; Dr. F. A. L. Lockhard, of Montreal, and Dr. G. J. Evans, of Montreal, will all three be present and contribute papers.

**Ontario Medical Council.**—The Ontario Medical Council has been meeting in Toronto during the past week. The following officers were elected for the ensuing year: President, Dr. J. A. Robertson, Stratford, Ont.; Vice-President, Hon. Dr. Sullivan, Kingston, Ont.; Registrar, Dr. R. A. Pyne, Toronto; Treasurer, Dr. H. W. Aikins, Toronto. A great deal of discussion took place upon the report of a special committee on legislation which suggested amendments to the Ontario Medical Act, which would be beneficial and timely both to the public and the profession at the present time. The Ontario Government will be memorialized to more clearly define what constitutes the practice of medicine. The object of this is to protect the public from the surfeit of quacks and healers which infest the Province at the present day.

**The Montreal Antituberculosis League.**—The investigation committee of the Montreal Antituberculosis League held a meeting one afternoon during the past week which was presided over by Dr. Roddick, M.P. Dr. Harding was appointed permanent secretary for the committee. A number of physicians representing the outdoor departments of the various city hospitals and dispensaries of Montreal were present and discussed with the Committee the cooperation of these institutions with the League. Each hospital representative addressed the meeting and reported that the institutions they represented would be willing and glad to cooperate with the League in reporting cases of consumption that came under their notice. Arrangements were completed, whereby each hospital would fully report the tuberculous cases coming under its care. This will greatly aid the League in its efforts to obtain information concerning these cases in the city and give them great opportunities in trying to stamp out the disease.

**Royal Jubilee Hospital, Victoria, B. C.**—The annual report for the year ending May 31, 1903, of the above hospital is as follows: The total number of in-patients treated this year was 784; the total number of out-patients 163; as against last year in-patients 782; out-patients 122. The total collective days' stay was 17,628, as against 17,531 for last year. The daily average number of patients in the hospital this year was 48.108, as against 47.27 last year. The cost of maintenance was $31,881.17, while the daily average cost per patient was $1.80. The Medical Superintendent urged increased accommodation for private patients.

**The Retirement of Dr. W. B. Geikie.**—Dr. W. B. Geikie, who for many years has been Dean at Trinity Medical College, Toronto, and Professor of Medicine in that institution, has resigned from both positions and will cease the active teaching of medicine. Dr. Geikie was well known as one of the most prominent teachers in medicine since 1856. He became dean of Trinity Medical College in 1878, a position which he has held for 25 years, and the great success which has attended that school of medicine was due in a great measure to his unceasing energy in its behalf. Dr.

Geikie has been succeeded as Dean by Dr. J. A. Temple, who is Professor of Gynecology in the same institution. Dr. Temple has also been appointed to represent the College on the Ontario Medical Council.

**A New Hospital for Vancouver, B. C.**—Vancouver will erect a fine new modern hospital to accommodate at the present time 100 patients and providing for the necessary executive offices. Toward this end the citizens have subscribed $30,000. The city has given $20,000, and the Government of British Columbia will contribute $20,000 in addition to these sums. Plans are under consideration for a building capable of being enlarged to provide for at least 300 patients, with all the appurtenances of a modern hospital.

## GENERAL.

**Appointment of Dr. Müller.**—Dr. Frederick Müller of Chicago, at one time assistant to Dr. Adolf Lorenz, of Vienna, has been elected Professor of Orthopedic Surgery at the Milwaukee Medical College.

**New Honors for Dr. Hemmeter.**—Dr. John C. Hemmeter has been elected to the Professorship of Physiology in the University of Maryland, of which institution he is a graduate, as well as of Johns Hopkins University and the Royal Gymnasium at Wiesbaden.

**Smallpox Hospital Burned in Orange, N. J.**—Fire on July 2 destroyed the main structure of the group of buildings, erected at Heywood and Mosswood avenues in Orange at the time of the smallpox outbreak about two years ago and used as an isolation hospital, entailing a loss of $2,000. It was with difficulty that the firemen prevented the destruction of the other buildings, as there are no hydrants nearby and the fight had to be made with the chemical engine. Both Health Inspector William Schluer and Fire Chief Hodgkinson think the building was set on fire.

**Berlin Medical Society Reports on Tuberculosis Experiments.**—The Berlin Medical Society assembled on July 8 to hear Prof. Kossel of the Imperial Health Office report the results of the prolonged experiments of the Tuberculosis Commission in infecting calves with human tuberculosis. Prof. Koch's observations, prior to the celebrated London address, caused the Health Office to appoint the Commission to make systematic experiments. Yesterday's paper was in the nature of a preliminary report. The Commission's investigations cover three forms of introducing tubercle bacilli in calves—first, subcutaneous injection; second, in food, and third, by inhalation. The preliminary report covers only the first form, but the experiments with the other forms continue.

The Commission decided to attempt the inoculation of calves not with matter taken directly from human victims, but with cultures made therefrom. The experimentation covered 39 separate cultures, 23 from adults and 16 from children. The results were that 19 calves subcutaneously treated did not show the slightest effect, 9 showed, after four months, the slightest changes of condition, and 7 showed more marked symptoms, but the propagation of tuberculosis in the body did not occur. On the other hand, 4 inoculations from tuberculous children infected calves with a disease which resembled a weak type of animal consumption, and 2 of this number died from tuberculosis. The Commission summarizes as follows: "The series of experiments strengthens Prof. Koch's view that animal consumption as the cause of human consumption does not play the rôle generally attributed to it, but definitive judgment requires further experimentation." In the discussion which followed Prof. Orth, the late Prof. Virchow's successor, strongly combated the view that human and animal consumption were dissimilar and non-transferable.

**State Medical Licentiates.**—The annual meeting of the State Board of Medical Examiners of New Jersey was held at Long Branch, July 6. The following candidates, who passed the State examination held at Trenton, June 16-17, were granted certificates of license to practice medicine in that State: Leon Hamilton Bossert, Millville; Arthur W. Belting, Trenton; Joseph Howard Cloud, Ardmore, Pa.; Francis R. Di Matteo, Newark; John Edward Donley, Jr., Orange; Harry Stokes Doriss, Atlantic City; Joseph William Dwyer, Passaic; Edmund Eastwood, Burlington; Walter Roland Elliott, Philadelphia; Mary E. Esser, Philadelphia; James Aloysius Gormley, Vineland; Earl Stephen Hallinger, Camden; Pomp. Long Hawkins, Atlantic City; Charles R. Heed, Philadelphia; William Thomas Hilliard, Jr., Salem; Howard Franklin Hoffmeier, Phillipsburg; Smith Hamill Horne, Atlantic City; Charles Albert Keating, Jr., Paterson; Raymond Arndt Kiefer, Midland Park; Joseph William Kenney, Philadelphia; John William King, Jr., Newark; Edward Isaac Leonard, Atlantic City; Fred Irvin Longstreet, Manasquan; John Carmelia Loper, Bridgeton; Harry George Macdonald, Hackensack; Calvin Edward MacMillan, Lakewood; Emil Mantner, Newark; Harold Philip Martin, Newark; Thaddeus P. Martin, Atlantic City; Charles Holmes Mayhew, Port Elizabeth; Dennis Ralph McElhinny, Long Branch; Frederick W. A. Mayer, Jersey City; John Lewis Meeker, Newark; James Percival Morrill, Paterson; Edward Ralph Myers, Atlantic City; Marcus Ward Newcomb, Newport; Jeremiah Francis O'Connor, South Amboy; T. Richard Paganelli, Hoboken; Edward Parry, Camden; Thomas Heritage Platt, Jr., Bridgeton; Jacob Wilson Reed, Pleasantville; Siegmund Albert Reich, Jersey City; Joseph England Roberts, Jr., Camden; Edward Bancroft Rogers, Mt. Holly; Horace Lewis Rose, Camden; Israel Jay Rachlin, Newark; William Satterer, Newark; John Berkey Seeds, Trenton; Frank Remington Sheppard, Cedarville; William Rice Silverstein, Newark; Howard Sedgwick Smith, Newark; Katherine Louise Storm, Philadelphia; Edmund Brewster Terry, Atlantic City; Claude Wellington Thomas, Medford; William Hibbs Tomlinson, Trenton; Helen Frances Upham, Asbury Park; John Van Ess, Paterson; Joseph Smith Van Dyke, Cranbury; William John Ward, New Brunswick; Victor Egbert Watkins, U. S. Army; Absalom Steelman Wescoat, Atlantic City; Herbert Heisler Wilson, Bridgeton; Emanuel Yadcowsky, Newark; J. John Lee Young, Newark.

The following candidates, having attained a general average of 90 or over, were placed on the Honor Roll: Francis R. Di Matteo, Newark, 92; Jeremiah Francis O'Connor, South Amboy, 92; Howard Franklin Hoffmaier, Phillipsburg, 91.1; Joseph England Roberts, Jr., Camden, 91.1; Joseph Smith Van Dyke, Cranbury, 91; James Percival Morrill, Paterson, 90.6; John Edward Donley, Jr., Orange, 90.1; William Satterer, Newark, 90, and William John Ward, New Brunswick, 90.

**Medicine as a Profession in Austria.**—The Medical Congress recently held at Vienna revealed a sorry, and at the same time anomalous condition of affairs in the Austrian empire. Twenty thousand communities, or 86 per cent. of all, are so poor that they cannot afford regular physicians, and 30 per cent. of the dead (in Galicia 75 per cent.) are buried without medical certificate. Yet, while there is such need of doctors, the number of medical students is decreasing at a surprising rate. Of every 1,000 students in the Austrian universities this year, only 132 are in the medical departments. The total number of medical students is

only 2,120 as against 5,277 in 1888-89—a decrease of about 60 per cent. in a little over a decade. And the decrease is likely to continue. At the congress referred to, Dr. Wichmann earnestly warned all young men against choosing the profession of medicine; which, he declared, the Government had practically killed by its faulty laws in favor of the laboring man. Other speakers dwelt on the same point. They were not opposed to compulsory insurance against illness as such, but to the manner in which it is managed and to the abuses to which it has given rise, and which call for prompt remedies. From the country communities good physicians have long been excluded, because they cannot be supported there, and now that already one-third of the Viennese are taken from private practice by the Krankenversicherung and its underpaid employees, the outlook in the cities becomes hopeless, too. Quackery naturally increases under such circumstances, and the medical man's resources are further cut off by the fact that, thanks to his own hygienic reforms, the number of cases of illness is now little more than one-half of what it was twenty years ago.

**Deficit in Cod-liver Oil Supply.**—From private correspondence it is learned that there is likely to be a very great scarcity in the supply of cod-liver oil during the coming fall and winter. One of the largest and most reliable refiners of this product reports that it is becoming almost impossible to secure it at any price, and thinks his concern will have to suspend operations for several months. Heretofore most of the commodity has come from Norway, because of its exceedingly high-grade quality and relative cheapness, but under present conditions, although quite as many cod are available in that country as formerly, it is found that the livers contain either no oil at all or too small a quantity to be made use of. The reason for this deficiency is unknown, but has been supposed by some to be due to the volcanic eruptions and other seismic disturbances which have occurred during the past year, since these are known to interfere with the procuring of proper food by fish of the cod type. This, however, is an extremely doubtful explanation.

The oil obtained from the Newfoundland cod is not of as good quality, is scarcer, and costs $200 to $250 a barrel, whereas the Norway oil has been obtainable in past years for about $40.

**Bound in Human Skin.**—It may not be generally known that the late Dr. F. Stockton-Hough, of Trenton, N. J., who left a valuable medical library in several languages, had a fancy for bindings made of human skin. He owned at least six books thus bound. One of them, "Catalogue des Sciences Médicales, Bibliothèque Nationale à Paris" (1857-73), is a large, very thick quarto half bound in skin from the back of a man. The texture is quite coarse and does not even suggest human skin. On the fly-leaf of a second book, "Cowper on Impregnation" (1789), the owner wrote: "Bound in leather tanned from the skin of the thigh of Maria L., affected with encysted trichinæ, who died of consumption in the Philadelphia Hospital. She was an Irish widow, aged twenty-eight years." Maria L. furnished the binding for another book also: "Das Buch der Liebe, oder das Geschlechtsleben in seinem ganzen Umfange." A valuable private library in New York contains a fourth book, presented by Dr. Stockton-Hough to the owner. This third piece of the leather-tanned skin of Maria L. is Barles's "Parties de la Génération." "Recueil des Secrets de Louyse Bourgeois," the famous French midwife, a 12mo, is the fifth book, also bound in the skin of Maria L. The sixth, Drelincourt's "De Conceptione Adversaria," a 12mo, is half bound in tattooed skin from the wrist of a man who died in the Philadelphia Hospital. Dr. Stockton-Hough tanned the skin himself in every case. That taken from the back, where the muscles are well developed, is coarse-grained; that from the thigh resembles pig-skin so much that the novice could not call it correctly by name. These books are now in the Medical Library of the Philadelphia Hospital, of which the Stockton-Hough collection is now a part.—*The Critic.*

**Anthropological Society of Washington.**—The 347th Meeting was held May 12. Dr. J. Walter Fewkes, who recently returned from the West Indies, gave a brief account of his work in Porto Rico and Santo Domingo, reserving a fuller presentation till next meeting. The paper of the evening was by Dr. E. A. Spitzka, entitled "Cerebral Characteristics of Distinguished Men, with special reference to the late Major J. W. Powell." Following is an abstract: Dr. Spitzka reviewed previous records of brains of distinguished men and proceeded to a consideration of their chief characteristics, particularly the brain-weight and the surface morphology—both generally and with special reference to certain cortical areas. Dr. Spitzka had tabulated the brain-weights of ninety-seven men eminent in the professions, arts and sciences; compared with the series of "ordinary" brain-weights collected by Bischoff and Marchand, there was a relatively and decidedly greater number of heavier brains in the former series. In a further analysis it was shown that the brains of men devoted to the higher intellectual occupations, such as the mathematical sciences, involving the most complex mechanisms of the mind, those of men who devised original lines of research (Cuvier, Cope, Agassiz) and those of forceful characters like Ben Butler or Daniel Webster possess the heaviest brains. The increase in brain-weight during evolutionary progress is directly related to the increase of cranial capacity along with the development of brachycephaly. As for the cerebral surface appearances, the highly intellectual man is likely to exhibit not only a superior degree of fissural and gyral complexity in general, but of certain cortical fields in particular. These differences in the extent of certain cortical (especially the associative) areas are palpable and measurable. Particularly important in this relation is the insula (Island of Reil), probably the purest association center in the brain, and usually showing a superior degree of development in men whose powers of speech were of a high order. The brain of Major J. W. Powell (to be described in the *American Anthropologist*) exhibited a decidedly superior degree of development. Its weight, 1,488 grams, was above the average of the 97 brains of eminent men, and for a man below medium stature and of rather small frame and whose age was 68, it was notably above the average. The most notable feature is a redundancy in the subparietal association area (especially the angular gyre) on the right side, a feature which may not be unrelated to an important characteristic of Major Powell's mental make-up: that of keen observation and superior powers of generalizing these. A large number of charts and figures of brains of notable persons illustrated the paper.

In discussing the paper Dr. Frank Baker held that the convolutionary pattern of the brain is due to the needs of motor activity, and any conclusions from it as to brain power should be carefully weighed.

Professor W. J. McGee stated that Major Powell's strength lay in generalizing on observations in nature and that the address of Dr. Spitzka shows that it is now possible to trace a definite relation between cerebral structure and the psychical character of an individual. Dr. Ales Hrdlicka said that it is a well-known fact that every organ in the body, if more than

ordinarily exercised, receives an augmented blood-supply and in consequence tends in time to increase in size and weight. It would be very strange if the brain formed an exception to this law. It is true that the efficiency of a brain may increase by the advance of the differentiation of its minute elements, but in all probability this and actual growth go hand in hand, and the size and weight of the brain must be of considerable importance in the study of the organ. That no very definite results in this respect have as yet been generally arrived at is due to the fact that we are practically only in the beginnings of brain study and need many additional accurate data on normal material, and that not only in white but also in various more primitive peoples. We need many further data on the significance in brain study of race, sex, stature, muscularity, age as well as other factors. The significance of the convolutionary pattern is particularly in need of further investigation, yet it is a general opinion that a marked complexity of the convolutions goes with the superior brain and vice versa. Dr. Hrdlicka expressed a hope of establishing in the course of time a valuable brain collection in his division in the U. S. National Museum.—*Science.*

**Obituary.**—Dr. Thomas M. Rochester, who had practised in Brooklyn for twenty-five years, died on Sunday of consumption in the home of his mother, in Rochester, N. Y. His great-great-grandfather, Col. Nathan Rochester, was the founder of that city and some of his descendants have lived there ever since. Dr. Rochester settled in Brooklyn soon after his graduation from the Buffalo Medical College, and remained in practice there until the breaking down of his health, three years ago. He was prominent in the various medical organizations in Kings County and a member of the Oxford, Marine and Field and Reform clubs.

## SPECIAL ARTICLE.

### BYWAYS OF MEDICAL LITERATURE.—XV.

#### AN AMERICAN MEDICAL INCUNABULUM.

WHILE in New Orleans we had the pleasure of seeing what is surely one of the most precious bibliophilic treasurers of American medical literature. It is a true incunabulum of medical printing in America, being the first book ever printed and published in New Orleans. It is in the possession of Mr. T. P. Thompson, whose choice collection contains more of the important Americana relating to old Louisiana before and after its acquirement by the United States than any other private library in the country.

The book is a little work on medicine whose title is Medicamens et Precis de la Méthode de Mr. Masdevall Docteur Médecin du Roi d Espagne Charles IV. pour guerir tautes les Maladies Epidemiques, etc.—that is Remedies and a Brief Description of the Methods of Mr. Masdevall, Doctor in Medicine to the King of Spain, Charles IV., for the cure of all epidemic diseases. As the little book contains less than 100 pages the assumption that it contains remedies for all epidemic diseases is a striking assurance on the doctor's part. This is not all, however, for the title proceeds—and for the cure of putrid and malignant fevers of different kinds and for protection for them. Price, four escalinos. To be obtained at the establishment of Louis Duclot, Printer, at New Orleans, 1796, with permission of the government. The dedication is to Baron Carondelet, the Spanish Governor, at the time.

The most curious thing about the book is the utter confidence with which the author promises that his remedies will cure, not alone relieve, but absolutely cure, the severest forms of fevers. The modern physician is at once tempted to find out, if possible, what are the precious ingredients of these wonder-working prescriptions. He is scarcely surprised, however, to find that they are only ordinary drugs, most of them now used very commonly in so-called family remedies; practically all of them inert, though there is an appeal to antimony in various forms, on all possible occasions, that shows the desire of the doctor to give and the wish of the patient to take something that would have an immediate and striking (not to say moving) effect. Tartar emetic, butter of antimony and the antimonial mixture were evidently the old doctor's standbys in the treatment of fever, though there is also an opiate febrifuge that was apparently often prescribed. Cream of tartar was employed at the beginnings of fevers partly for its laxative and partly for its diuretic and diaphoretic effects. The practice of using it thus has not gone out yet, among the older physicians of the South especially, and might well be imitated by their younger colleagues. Among the simples employed for colds and the combination of which was guaranteed to be a sure cure for consumption (when did they not have a cure for consumption—in spite of the mortality) was a mixture of the decoction of coltsfoot, of the wild poppy, of creeping ivy (hedera terrestris), of maiden hair fern, and the finest honey. Curiously enough, the time for special medication in Dr. Masdevall's opinion was not the spring of the year, but the fall. After all, perhaps, it is not surprising that it was after the oppressive heat of the summer rather than their pleasant winters that the inhabitants of old New Orleans felt the sluggishness that is supposed to be an indication for active medication. The ingredients of the autumn medicine were the inevitable antimonial mixture some Rosolidi Kina (a mysterious drug of a century ago) and syrup of vinegar. The old doctor's confidence in his remedies must have been one of the most effective factors in the treatment of his patients if he really effected the cures he claims so glibly to be the sure result of his wondrous prescriptions.

#### AS OTHERS SEE US.

AMERICAN publications of all kinds have taken the occasion to say so much about Prof. Lorenz during the past few months, because of his pleasant visit to us, that it is not surprising to find that the good Doctor had something to say of us on his return to Vienna. At a meeting of the Doctors' Club, of Vienna, he made some remarks as to the peculiar customs he had noted in America. He deprecated especially the notoriety that had been given to him, since it prevented his moving around as freely as he would otherwise like to have done, since everywhere he went he immediately became the subject of remark. He had to deny himself the theater almost completely, though with true Viennese Gemüthligkeit he would have liked very much to have gone frequently.

One of the customs he found most difficult to understand in America is our habit of having our shoes shined in public. As the correspondent of one of our prominent New York dailies said in comment: "To the fact, or to what he thought was the fact, that we generally have this operation performed while the shoes are on our feet, he devoted almost as much space as to anything else he saw over here, which shows that a trifle that never would have entered our thoughts struck him as a most curious and interesting novelty. 'I have often,' he writes, 'put the question to Americans, why, if time is money, is it absolutely necessary for me to be present every morning when my shoes are being cleaned?' I would say: 'Why must I have my shoes on my feet when these are being cleaned and thereby unnecessarily lose a quarter of an hour's time?' The answer would be: 'Yes, it is curi-

ous, but that is the custom.' The dear personnel of the hotel had other things to do of greater importance. If you want to have your shoes cleaned you must go to the negro, or clean them yourself. Therefore, I would advise every one who intends to visit America to supply himself in advance with the necessary utensils for shoe cleaning, if he prefers his independence to his convenience. Then follows the queer statement that 'it may be interesting for the visitor to the University Club'—what University Club not specified—'to know that the cleaning of a pair of shoes in America is dearer than a dinner in this club. It is easy, therefore, to compute how quickly under such circumstances the cleansing would exceed the original cost of the shoes. Cleaning shoes is no bad business in America, and supports a man well.' Apparently the good doctor was very savagely 'touched' by the bootblack at some club, and acquired some wrong ideas therefrom. But, come to think of the matter, it certainly is strange that such a vast amount of valuable American time should be wasted in the way that troubled Dr. Lorenz, and, thinking again, there has been an unrecorded change of late years in the shoe-cleaning habits at hotels, if not in homes."

All of which goes to show that sometimes we need to see ourselves as others see us, if we would behold the real selves. Physicians must feel our absurd time-wasting custom in this matter more than others. Why should it continue?

### THE SACRAL SPOT IN CERTAIN RACES.

Those who are interested in the occurrence of various malformations and peculiarities in the sacral region will be attracted by the results of some observations of Frederic Starr among the Maya Indians in Mexico. It is well known that among the Japanese and other populations of the East as well as the Esquimaux and certain of the Chinese of the northeastern part of China, a distinctly pigmented spot exists over the sacrum in all children. This disappears sometimes during the course of the first year and practically always before the child has reached the age of two years. It is understood to be the result of the closing in of tissues over the cleft that exists in this region in the embryo and whose imperfect closure leads to the many anomalies that are known to occur over the sacrum.

Mr. Starr said that it is a tradition that every pure-blooded Maya Indian has a blue or purple spot upon his back in the sacral region. Observation among adults, however, failed to show its existence. An opportunity was presented to examine a number of children and in the series of cases the spot was found in every subject of pure Maya blood. The spot was not found, curiously enough, among mestizos, that is those of mixed blood. It is very evanescent among the Mayas, being very rarely found among individuals of more than ten months of age. The spot is variable in size, shape and position, but is always in the sacral region. In color it is blue or a bluish purple. The whole subject is interesting as showing some explanation of the many pigmentary and hirsute anomalies found among other races.

### VIVISECTION AND MORAL PRINCIPLES.

In the April number of *The Messenger* (New York), there is an article with the title "Is Vivisection Morally Justifiable?" which discusses the moral principles underlying the employment of animals for experimental purposes in order to obtain information with regard to disease and its prevention and cure. The article is written by Rev. Charles Coppens, S. J., the author of a text-book on Moral Principles and Medical Practice, and a lecturer on medical ethics at the medical school of Creighton College, Omaha, Neb. The article contains an excellent résumé of the objections urged on supposedly moral grounds against the practice of vivisection and shows the lack of basis for antivivisection argument. For those who are interested seriously in the subject, and who sometimes wonder whether there may not be some truth in the frequently asserted claim that vivisection is cruel and in itself immoral, the article will present a very satisfactory answer to doubts and difficulties.

Professor Coppens begins his statement of the subject by quoting the letter of Professor Keen, of Philadelphia, addressed to Senator Gallinger, and which stated the ground on which the medical profession demand that no bills shall be introduced into Congress limiting the practice of vivisection because of the hampering effect which such legal regulation would have upon the progress of medicine in this country, as it has already had in England. There is after this a very fair statement of the ethical objections usually made to the practice of vivisection with the answers to them. The Rev. Mr. Coppens' conclusion is as follows:

"Such appeals to sentiment rather than reason are constantly met with in antivivisection literature; but they are an unfair presentation of the real state of the question. While it may be pleaded that even one man's life is worth the sacrifice of many brutes—according to the saying of the gentlest of teachers, "Are you not of much more value than they?"—there is a stronger plea than this. For the purpose of vivisection is the saving of thousands and myriads of men from sufferings more exquisite than any brute can undergo; for mental anguish is far more painful than physical hurt. Let any sensible man compare in his mind the suffering and death of a horse or a dog, with the scene presented by the death-bed of a father or mother of a family, with the prospect of leaving the children orphans, and exposed to the ills of poverty and moral neglect, or the contagion of bad example. Then let him consider how many persons have been rescued from the approach of death by the assiduous labors of learned physicians who, but for vivisection, would have been powerless to afford assistance. There are living to-day countless poets, artists, statesmen, doctors, soldiers, clergymen, magistrates, etc., and multitudes of mothers of families whose lives would have been lost in sickness, or by wounds, or in the labors of childbirth, if vivisection had not furnished the knowledge which enables medicine to prolong their lives."

### PARASITES AND PEARLS.

Recent investigations have shown that most of the calculous formations within the human body are due to morbid processes set up by the presence of bacteria. It is now generally accepted that practically all the biliary calculi are due to the presence of bacteria and these bacteria can even be recognized by staining and other methods in the center of the calculus. In fact, calculi have been produced in animals by the introduction of bacteria into the gall-bladder. Pancreatic calculi are also thought to be due to bacterial action. The various calcereous degenerations within the body are also now recognized to be the result of the chronic inflammation due to the presence of bacteria and nature's conservative effort in effectively walling off such micro-organisms so as to prevent their getting into the lymphatic or blood circulation.

Some recent observations reported in the English scientific weekly, *Nature*, seem to show that the formation of pearls instead of being due, as has been thought, to the presence of any irritant, are due to a specific parasite which, after having gained an entrance into the shell of the pearl oyster, sets up a special irritation that results in the deposition of the pearly material in the globular shape so familiar to the lover of jewelry. Other irritants, it is well known, will cause the deposition of

this material but never in the beautiful form which it takes as the result of the presence of the parasitic worm described by recent observers. The Japanese are accustomed to obtain little pearly images of Buddha, by depositing metal models of the god in the shells of pearl oysters but these are scarcely more than pearly in appearance and cannot be spoken of as true pearls. The present discovery will, it is said, revolutionize the pearl-fishing industry by making it possible directly to control the formation of the precious stones on the fishing beds.

NUTMEG AS POISON AND ABORTIFACIENT.

AN English practitioner recently reported a case in which a whole nutmeg was taken with the idea of producing abortion or at least bringing on menses delayed in a case with suspicion and fear of pregnancy. The result was severe symptoms of narcotic poisoning. His communication is worth giving in brief, for its interest. We quote it from Squibb's *Ephemeris*, Vol. VII., No. 1, 1903: "Quite recently I was called during the night to see a young woman who was stated to be 'in a fit.' I found her in a collapsed condition, muttering unintelligibly; her extremities were clammy, her pulse was hardly perceptible, and her pupils were somewhat dilated and reacted feebly to light. The symptoms were suggestive of alcoholic poisoning but her breath smelt unmistakably of nutmeg and I then elicited that she had taken a whole nutmeg, grated, in a wineglassful of gin an hour or so previously. On asking her friends why she had done this I was told that 'she was so afraid of having another child.' It appeared that the catamenia had been delayed two weeks and, dreading pregnancy, she had taken the advice of some female friend with the result above mentioned. I afterward made some inquiries and learned that there is a prevailing impression among the domestic servant class that nutmeg is an emmenagogue, although such a large dose is perhaps unusual. Her general condition improving I contrived to empty her stomach of its contents. She remained in muttering delirium throughout the night and slept heavily nearly all the next day, when she awoke apparently recovered. The catamenia followed accompanied by much pain.

The impression that nutmeg and, curiously enough, this time, too dissolved in gin, is an abortifacient is evidently not confined to England, for in the London *Lancet*, Vol. I., 1902, p. 1798, Dr. S. Maberly Smith, of Geelong, Victoria, Australia, reports a similar case. As it is not unlikely that the tradition in this matter has penetrated also into America, we quote the details of the Australian case also:

"Some years ago I was called to see a woman who had taken the whole of a ground nutmeg mixed with gin. The symptoms were exactly the same as those described by Mr. Pitter, and the woman nearly died. The dose was taken to procure abortion; whether it had that effect I did not learn. The friends volunteered the remark that the woman had taken the nutmeg in spite of the fact that a neighbor had nearly died from the same cause shortly before. At the time I asked a good many friends, medical and lay, if they knew anything of the poisonous properties of nutmeg in large doses. None of them did except one old lady from the north of England, who stated that she and people in her part knew them well. Squire states that nutmeg in large doses is a narcotic poison."

---

**Typhoid at Ithaca.**—Following the energetic work of Dr. Geo. Soper on the water supplies of Ithaca, typhoid had been practically eradicated. This week, however, some new cases have developed, and at the present time there are 9 patients with the disease.

## SOCIETY PROCEEDINGS.

### NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

*Stated Meeting, held May 5, 1903.*

President, Wm. Egbert Robertson, M.D., in the Chair.

**Treatment of Tapeworm.**—This was the subject of the paper read by Dr. Samuel P. Gerhard, in which he called attention to the three specimens which were most commonly met with, *i.e.*, the beef tapeworm or *Tænia saginata*, the pork tapeworm or *Tænia solium*, and the broad tapeworm or *Bothriocephalus;* the former being the one most commonly met with in this country. He called attention to the necessity of thoroughly cooking the meat before it is eaten, which, together with cleanliness on the part of those engaged in handling it, and systematic and regular inspection of the cattle and the meat after it is in the market, he believed would materially decrease the number of cases of this condition. He remarked upon the difficulty in removing the worm and considered that the treatment which was applicable to worms of one character was applicable to all. The preparation of the patient prior to the administration of the remedy he considered a most important factor. The patient should be required to fast for twenty-four hours before the medicine is administered, during which time the bowels should be thoroughly emptied by means of purgatives. Among the drugs mentioned were the male fern, kouso (the latter being liable to produce severe nausea and vomiting in some cases), the bark of the pomegranate, together with its alkaloid, pelletierine. The last two, however, are very impalatable and may produce toxic effects in doses large enough to be effective. Oil of turpentine was formerly used to a great extent, but owing to its nauseating taste and difficulty of administration has somewhat fallen into disuse. Kamala is a very active drug, but its use is contra-indicated, because it causes nausea and vomiting in many instances. Powdered pumpkin seeds were thought to be a valuable and harmless remedy, especially in children. He emphasized particularly the importance of removing the whole worm in all cases, as if the head or any of the segments remain it will develop again in from six to eight weeks. He believed that the great drawback to the administration of many of the remedies was the very large dose required, being in some instances as much as a pint of a bitter, nauseating liquid, to be taken at one or two draughts, necessitating loss of time, and being a very serious matter with a weak and debilitated patient. He reported a method which he had found very satisfactory. The patient is instructed to thoroughly clean out the bowels by purgatives the day previous to the administration of the remedy. In the morning, as early as possible, a 20-grain capsule of pelletierine tannate is given, and after this has operated fully, which is usually in about two or three hours, the following prescription is administered:

Olii Resinæ Aspidii.....drams, ij
Ether.....drams, ij
Hydrargyri chloridi mitis...grains, xij

This is divided into sixteen capsules and one given every ten minutes, no food being taken. In about two or three hours the worm will be expelled whole with its head intact. He stated that he had recently employed this method in seven cases with very satisfactory results, the depression is generally very slight and does not last longer than two or three hours, and if it does exist, light food can be administered after the worm is expelled.

**Intestinal Parasites.**—Dr. L. Napoleon Boston gave a microscopic exhibition of intestinal parasites,

consisting of the beef worm, *Trichina, Echinococcus* and *Anchylostoma*, the latter being the parasite which is supposed to be the cause of the anemia among the bricklayers and other people of the lower classes, in many instances, and which examination of our army in Porto Rico revealed that 30 per cent. of all the cases of anemia were due to this parasite.

Dr. A. C. Morgan, in discussing these papers, stated that he had used the remedies recommended therein with very satisfactory results. He believed that a positive diagnosis of tapeworm should not be made, unless the segments were found in the stool, although the larva are not discoverable there. He referred to the predisposition of the embryo of various worms to lodge in the pectoral muscles, the biceps, the diaphragm and particularly under the tongue, and in a patient suffering from what is apparently muscular rheumatism, but in reality larva, there will be irregular temperature, some fever, and increased pulse. Interference with the action of the diaphragm, tenderness of the various muscles and symptoms of pleurisy are also important diagnostic symptoms. He believed that the oil of turpentine was contra-indicated if the kidneys were not in perfect working order.

**Difficulty of Diagnosis.**—Dr. Samuel Wolfe referred to the difficulty of diagnosis of this condition, as the various forms of intestinal parasites do not give rise to particular symptoms, and the conclusion can probably only be positively reached after seeing a worm, and the condition may exist for a considerable time without any being passed. He felt that they were more apt to occur during some acute infectious disease, or some decided constitutional disturbance, especially when the disease has assumed the malignant form, he having observed in several instances during the infection worms were passed in very large numbers. In cases of tapeworm, he believed, if the worm was of any size segments would usually be discoverable in the stools.

Dr. Luther C. Peter referred to a publication which he had recently read attributing the poisonous effects to the castor oil, which was administered in most cases.

Dr. Gibbon reported the case of a child, who during the three or four months previous to the passing of segments had been given raw Hamburg steak. He also referred to a case which had come under his observation in the Children's Hospital, where a child was seized with coughing and the nurse removed one or two large worms from its mouth. He believed that the migration of the worms was particularly common in typhoid fever, in some cases causing the perforation.

Dr. Harry Lowenburg reported the case of a Polish child which was brought to him a short time ago suffering from hematemesis. Being familiar with the fact that these people fed their children on raw pork, he at once administered an emetic, which was followed by the vomiting of a large round worm, about four inches long, after which all the symptoms disappeared.

Dr. Charlott reported the case of a girl operated upon in the German Hospital, after which she vomited a large number of worms.

Dr. Arthur P. Hitchens suggested the possibility of the remedy being absorbed before it reached the intestinal tract unless it was given in capsule form, which method he believed would be the most efficient.

Dr. Wm. Egbert Robertson recommended the more frequent examination of the stools, which he believed would lead to the detection of the ova of the round worm in many instances. While the flat worm is rare in children, he referred to a case reported by Dr. D. J. Milton Miller, occurring in a child eight months old, which was supposed to be infected by feeding it on expressed beef juice.

Dr. L. Napoleon Boston, in closing, stated that in cases of trichina there is always a swelling and pain in the frontal region. He believed that the *Oxyuris vermicularis* was quite as common in adults as in children, and while the habits of the patient may have a great deal to do with its occurrence, he did not feel that the social class had. Examination of the rectal mucus prior to the commencement of treatment was recommended in all cases.

Dr. Samuel P. Gerhard believed that many cases were diagnosed as *Tænia solium*, which in reality were worms of a different character. He believed that the reason this condition was not so prevalent in this country was due to the fact that people had been taught to cook pork thoroughly, while they eat raw beef, which accounts for the more frequent occurrence of that variety. Ether he believed to be of value as it tended to stupefy the worm and in that way facilitate its removal, and he also felt that it was important that the worm should be passed into a vessel of warm water, as if the temperature is lower than that of the intestinal tract it is liable to recede.

*Stated Meeting, held June 2, 1903.*

The President, Wendell Reber, M.D., in the Chair.

SYMPOSIUM ON EPILEPSY.

**"The Treatment of Epilepsy"** was the title of a paper read by Dr. Luther C. Peter, in which he directed attention to the fact that the treatment of the disease must be largely prophylactic, first by preventing the causes which give rise to the convulsion and, second, by preventing the subsequent convulsions, with the consequent mental and physical changes. He believed that much more could be done for the patients by careful attention to the diet, daily bath, sleep and environment, especially in children, than by medical measures, and these measures are particularly important if the child has a neurotic predisposition. He stated that after observing over 2,000 cases of nervous disorders in children in his Clinic at St. Joseph's Hospital, and in private practice, he believed tea and coffee acted in many cases as inducing factors, and in some cases were the only causes of epilepsy in children; the great amount of mental work done by children with the present school system, he believed also was accountable for a considerable number of these cases. After the epileptic habit is formed, he believed the general management of the case to be just as important a factor, and while he believed that drugs played an important rôle in the cure of these cases, he felt that the general management was the most important factor of every complete recovery. The food should be chosen with especial reference to the individual requirements of the patient, and the condition of the digestive organs, and as a rule any easily digestible and assimilated food may be employed, provided its use is not followed by gastro-intestinal disturbance, as deranged stomach or intestinal fermentation is liable to produce a convulsion. If the patient's occupation does not particularly require meat, it is a good plan to restrict the amount taken. The author recommended the closest scrutiny of all parts of the body in order to detect any cause for the epilepsy and stated that he had seen cures follow the correction of refractive errors, removal of adherent foreskin, removal of constipation, etc., the success depending entirely upon the early recognition of the condition and removal of the cause. The toxic form, including the alcoholic type, he believed to be especially amenable to general treatment. It is pretty generally conceded that the convulsion has its origin in the cortical cells, and, therefore, the class of drugs which do the most good are nerve sedatives, the drug most exten-

sively used being the bromide salts. He stated that he believed in many instances the mental dulness was due more to the excess of the bromides than to the epilepsy and referred to the fact few patients could take this remedy in larger amounts than 30 to 40 grains per day without producing bromidism; the addition of several drams of infusion of digitalis often intensifies the sedative action, without aggravating the bromidism; a minim or two of Fowler's solution will prevent the acne. Chloral will act beneficially for a time in controlling the convulsions and if the patient has mental warning of the approach of an attack and it is given in sufficiently large doses it will often prevent the convulsion. He stated that he had used the fluid extract of solanum in a considerable number of cases, and in adults had found that as good results could be secured with from 2 to 4 drams of this drug as from 10 to 15 grains of potassium bromide, and its use can be continued indefinitely without the depressing mental effects. Its use has been followed by equally gratifying results in children, who usually stand the bromides so poorly. In those patients who have a considerable period of premonition, inhalation of nitrite of amyl is of much value.

**"The Diagnosis of Atypical Epilepsy."**—This was the title of a paper read by Dr. A. C. Buckley, in which he called attention to the necessity for early diagnosis and correction before the nervous mechanism had formed the epileptic habit. After giving in detail the symptoms of a typical attack of epilepsy he stated that there were many cases which were not recognized for months or perhaps years, owing to the fact that the attacks may be of such a nature as not to be noticed by the patient or his family, or may occur only during the sleeping hours, when, except for the fact that he feels fatigued and has marked muscular soreness upon awakening, the patient, when he seeks medical advice, is not aware of his true condition. He believed that the minor attacks were less responsive to treatment than the major attacks, although there is no strict line of demarcation between the two. The minor attacks usually consist of momentary unconsciousness which very often is not recognizable, and it is in these minor attacks that the greatest deviation from the set symptoms occur. Nocturnal epilepsy, when the symptoms are not sufficient to be recognized by the patient, can only be diagnosed by the after-signs, such as soreness of the tongue, usually on one side, frequently bloodstains on the pillow, if the tongue has been bitten, minute conjunctival extravasations, voiding of urine in bed, and even these are frequently absent. He believed that a confusing factor in diagnosis was the differentiation between the minor epileptic attacks and syncopeal attacks; the epileptic attacks occur independent of the surroundings and in the absence of any predisposing causes, such as emotion, physical exertion, overheated rooms, hot, humid weather, etc., which frequently produce syncopeal attacks. In the latter condition there is usually an irregular pulse and clammy skin which is not present in epilepsy. In epilepsy the loss of consciousness is sudden and complete and returns quickly, while in syncope it is usually preceded by a subjective feeling of faintness. Epilepsy may be preceded by an aura which may be described as a feeling of faintness, but there is usually associated with it a sensation of fear or strangeness which is not present in syncope. Distinct vertigo is in favor of epilepsy, although care must be taken to distinguish the vertigo from dizziness, which is sometimes present in syncope. He considered the automatic type of epilepsy of great importance. He believed that hysteroid could usually be distinguished from epileptic seizures by the fact that the former are usually coordinated.

**Etiology of Epilepsy.**—Dr. Charles W. Burr referred to the fact that the etiology of epilepsy was still very much in the dark, and believed that the greatest hope lay in the prevention rather than the cure of epilepsy, and in children predisposed to this condition, it is especially important that they should live out of town, have nourishing food and avoid mental overwork. He believed that alcohol played a considerable rôle in the production of epileptic seizures and reported the case of a shoemaker, who would have attacks only after a drunken debauch. He felt that many of the cases of dementia were much accentuated by the long-continued use of bromides, and while he had not attained very good success with horse-nettle, thought this fact could probably be accounted for in that he had not given it in sufficiently large doses. In regard to diet, he did not believe that the patient should be required to forego red meat altogether, although he felt that its use should be restricted. He referred to several cases of postepileptic automatism, one man would go through the motions of pulling a rope for three or four minutes very time he would have an attack, and he expressed the opinion that in some instances this condition was responsible for the perpetration of innocent crime.

**Careful Study of the Aura.**—Dr. Samuel Wolfe, felt that a careful study of the aura in connection with the sensory nerves might reveal something in regard to the etiology of the condition and expressed the opinion that the attack originates in the peripheral sensory nerves rather than in the cortical cells. He referred to the fact that a large number of curious conditions have been recognized as epileptic equivalents, directing particular attention to the fact that an Italian writer had recently advanced the theory that a good many of the cases of tachycardia are really cases of epilepsy, and reported a case of tachycardia which had recently come under his observation, which he rather inclined to think was of this class. In the treatment of epilepsy he believed the bromides to be the foremost remedies, and if bromidism occurs, the addition of one or two drops of Fowler's solution with each dose is of value. Atropine is also frequently of advantage in conjunction with the bromides.

**Pupillary Incoordination and Hypermetropic Astigmatism.**—Dr. Wendell Reber stated that he had made a careful study of the ocular condition of about fifty epileptics for about a year, and found pupillary incoordination in about one to three. Optical imbalance in about 35 per cent. and in a good many hypermetropic astigmatism was present. He did not attach much importance to these eye conditions, however, as all of them frequently exist in other conditions. He referred to the fact that the majority of epileptics were great overfeeders and not very active.

Dr. Lewis H. Good reported a case of a man who became intoxicated and after he went home fell over in a fit; after this was over he was very violent for about an hour, breaking up furniture, etc., after which he fell into a deep sleep or comatose condition. He also reported another case, apparently hysterical, in which the symptom is incessant talking for about half an hour, the acts being both nocturnal and diurnal. The patient was run over by a wagon when a child and at puberty had amenorrhea and dysmenorrhea, since which time she has had these attacks.

Dr. Solomon Newmayer referred to the rarity of the occurrence of epilepsy among the Hebrew race. He reported the case of a man who was suddenly taken ill on a very hot day; he became unconscious had a temperature of 104° F. and spermic fever was suspected and the usual treatment applied. After about an hour he revived, the case proving to be one of epilepsy.

J. Frank Wallis reported three cases of convulsions, one of which he attributed to the patient eating cabbage, the other to eating sausage and pretzels, and the third to the fact that the patient had eaten a very hearty dinner. All of these cases were relieved by rectal injection, and the suggestion was made as to whether they were cases of true epilepsy or not.

**Removal of Obstructions of the Nasopharynx and the Ear.**—Dr. Nathan G. Ward referred to cures that had been reported by the removal of obstructions of the nasopharynx or by the removal of obstructions from the ear, the condition in most of these cases being obstruction or deflection of the septum, adenoids, enlarged tonsils, and a few cases of pharyngeal abscess and suppurated ears. He believed that the greatest good could be secured by the use of prophylactic measures tending to prevent the attacks.

**Cold Water Treatment.**—Dr. Charles C. Biedert reported the cases of two brothers, both of a neurotic temperament, in which the attacks were frequently superinduced by disputes with their wives; in which the cold water treatment was administered with gratifying results. He also referred to a case caused by alcoholism which was benefited by this same method.

Dr. Howard S. Kinne felt that a very important factor in the prophylactic treatment of epilepsy was the placing of all infants on a properly nourishing diet, as nearly similar as possible to the mother's milk; and believed that one reason why epilepsy was less frequent among the Hebrew race was owing to the fact that the mothers usually nurse their children. He did not believe that alcohol played a very important part in the production of epilepsy in the subject itself, but was more manifest in his descendants.

**Convulsive Attacks Produced by Bradycardia.**—Dr. William Egbert Robertson called attention to the fact that convulsive attacks produced by bradycardia are very similar to the epileptic seizures. He believed that too often convulsions in children were attributed to teething and very little attention was paid to them, which he felt accounted for at least some of the cases of epilepsy. He felt that tea and coffee played but a small rôle in the production of epilepsy in those not predisposed to the disease.

Dr. Luther C. Peter, in closing the discussion, stated that he did not believe solanum to be any better drug than bromide, but its greatest merit consisted in the fact that it could be given in sufficiently large doses to benefit the patient for a long time, without producing any mental effects. In regard to alcohol as a causative factor, he stated he had three cases under his observation at the present time who were subject to the seizures only after a debauch, but did not feel prepared to say that this was the cause of the epilepsy.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting held April 7, 1903.*

The President, Pearce Bailey, M.D., in the Chair.

**Birth Palsy—Syringomyelia.**—Dr. Edward D. Fisher presented a man, twenty-five years of age, who had had a birth palsy, apparently the result of a tedious labor and a forceps delivery. There were present the characteristic athetoid movements, but the epileptic attacks had ceased in childhood. When fifteen years old he began to notice a wasting of the muscles of the left hand and forearm along with some disturbances of sensation. Subsequently the right hand became similarly affected. On examination, there was found to be almost complete loss of pain and temperature sense, and the tactile sense was not good. There was no sensation on either side to the strongest faradic current. There was absolute loss to both the faradic and galvanic currents in both hands. In the forearm there was a diminished reaction. The condition just described had progressed slowly during the past ten years. The reflexes were greatly exaggerated on both sides. The case had been previously diagnosticated as progressive muscular atrophy, but he would make a diagnosis of syringomyelia, quite probably originating in a slight spinal hemorrhage. The patient was very intelligent and in perfect health. He had presented no bulbar symptoms.

Dr. B. Sachs thought the association of syringomyelia with an infantile cerebral palsy was unique. The suggestion of a hemorrhage occurring simultaneously into the cervical portion of the cord at the time of the cerebral palsy appeared to him a good one. Recently cases of congenital spastic paraplegia had been reported which were known to have been produced by hemorrhage into the cord lower down. The speaker said that a few days ago he had seen a case of apoplexy in an elderly person resulting in a left-sided hemiplegia. After a few days very slight motion returned in the left hand, and he was astonished to find that he could secure fairly good motion of the paralyzed hand when asked to close the other hand. This observation was a common one in children, but he had not before noticed it in adults.

Dr. Pearce Bailey said that a few years ago Schultze described hemorrhages into the spinal cord occurring in young infants in connection with difficult labor, and the subject had assumed a medicolegal interest. In the cases of hematomyelia that he had seen he had never been able to observe them long enough to see the progression of the symptoms.

**Suture of Popliteal Nerve: Perfect Restoration of Function.**—Dr. Russell A. Hibbs presented a boy, fifteen years old, who had come to the Orthopedic Hospital on October 6, 1902, with a history of having fallen upon a knife several weeks previously and injured the leg. On October 9 he was operated upon, and on exposing the site of the injury it was found that the popliteal nerve had been divided. It was accordingly sutured with a practically perfect result. While the voluntary power in the muscles supplied by this nerve was lost there was still some sensation, which was apparently accounted for by the fact that a few fibers of the nerve remained intact. The limb was kept slightly flexed for six weeks after the operation.

Dr. M. Allen Starr thought surgeons as a rule did not recognize the great importance of suturing nerves at the time of such injuries, for, it was not uncommon for persons so afflicted to seek relief a considerable time after the injury. There could be no question that a divided nerve would not unite spontaneously in the majority of cases, and it was equally certain that by nerve suture a good result was usually secured. He had seen one or two interesting cases in which nerve suture had been essayed in children in whom the brachial plexus had been injured at birth. Four successful cases of this kind had been recently reported. The operation consisted in laying bare the brachial plexus, finding what nerves were torn and uniting them.

Dr. William M. Leszynsky said that in injuries of the hand special care should be taken to determine whether or not the nerves had been injured. He had recently seen a case in which the divided tendons had been sutured and the divided ulnar nerve had been entirely overlooked. As a result, a neuritis of this nerve had developed before he saw the case. Although rather late an operation had been advised in the belief that even late operations were often successful.

Dr. Fisher said that he had had under observation for some time a facial paralysis that dated from childhood,

the patient being a woman of thirty. After awhile a faradic response from the facial muscles was obtained; hence, he thought one could hardly place a time limit after which nerve suture would afford but little prospect of benefit.

Dr. Hibbs said that in his case the original wound had been sutured at a hospital, but the nerve injury had not been noticed.

**Paralysis Agitans (?)**—Dr. J. Ramsay Hunt presented a man of forty-three years, a cigar roller by occupation. The present affection dated back four years. It had first been noticed that the right hand was weak and tremulous, but he had continued at work for three years. Last July the head also became tremulous and the right leg felt heavy. When first seen, about one month ago, examination showed tremor of the right hand without rigidity; a slight atrophy of the right forearm; a tendency to monotony of speech and a rather expressionless face. The question arose as to whether this was an occupation atrophy or, as he was inclined to believe, a case of paralysis agitans.

Dr. Hunt also reported a case at the Montefiore Hospital which had presented the characteristic picture of paralysis agitans for several years before death. An autopsy of the brain was alone permitted. The vessels showed marked arteriosclerosis. There was an excessive degree of pigmentation and some rounding of the processes of the cells in the cortex and in the portion of the cervical cord removed for examination—in short, those changes that had been regarded as occurring frequently in paralysis agitans. The specimens were exhibited under the microscope.

**Elephantiasis Ossium.**—Dr. I. Abrahamson presented a woman, aged thirty-six years, showing a peculiar glossy appearance of the skin of the forehead and a remarkably wide supra-orbital ridge. Examination revealed a ptosis of the right eye, a double divergent squint and a marked contraction of both inner fields of vision. According to her husband, the changes in her outward appearance had been progressive. The malar bones were enlarged, and apparently the hands and feet were growing larger. The condition was possibly due to luetic disease of the apophysis because there was specific disease of the eyes.

Dr. Starr remarked that the appearance of the eyebrows pointed strongly to the case not being one of acromegaly or myxedema, but of elephantiasis ossium. The case appeared to be in an early stage.

Dr. Leszynsky said that acromegaly could be excluded by the condition of the visual field, as in that disease there was usually a bitemporal hemianopsia.

**Paralysis Agitans—Discussion.**—Dr. B. Sachs said that he was of the opinion that this was distinctly a disease of the senile period. In this period the two most important factors were emotional excitement and some prolonged and exhausting disease. The point of differential diagnosis to which Charcot had attached so much importance, the non-involvement of the head in paralysis agitans and its involvement in multiple sclerosis, seemed to him a point not well taken, for he was sure he had seen involvement of the head in fully 75 per cent. of cases of paralysis agitans. Charcot's attempt to differentiate sharply between these two affections seemed to him to have been carried beyond a justifiable limit. He had seen cases giving the symptoms of multiple sclerosis, and yet later on develop a distinct picture of paralysis agitans. There was a young man at the Montefiore Hospital whom he had first seen when only about eighteen years old, and who developed the typical carriage, tremor and speech of paralysis agitans. As the years went on he developed nystagmus and a marked exaggeration of all of the reflexes, and his speech was now as much that of multiple sclerosis as of paralysis agitans. He also recalled the case of a young woman first seen by Professor Mendel in Berlin, who made the diagnosis of hysterical tremor. When seen by the speaker, a few months later, she presented what appeared to be the first symptoms of multiple sclerosis. At the present time, she presented the typical picture of paralysis agitans. This experience led him to think that there must be some relationship between these two diseases, and the case presented this evening by Dr. Hunt gave color to this view. With regard to the treatment of paralysis agitans he was accustomed to make use of hyoscin and the ordinary sedatives, and probably all present believed that no drug did much good. The only treatment that was fairly satisfactory was the use of some form of vibratory therapeutics.

Dr. Stuart Hart said with regard to the records of Dr. Starr's clinic at the Vanderbilt Clinic, that out of 219 cases of paralysis agitans there recorded 139 were males and 80 females. Under thirty years of age there developed 2 cases, both males. The disease commenced in 88 cases between fifty and sixty years of age. Among heavy workers there were 45 males; among those particularly exposed to cold there were 24 cases; among the lighter trades there were 24 cases; among those working in factories were 14 cases. In 6 cases it was stated that the mother had paralysis agitans, and in three the father was said to be so affected, while in several other cases brothers or sisters were said to be similarly affected. Forty patients believed that the disease arose from anxiety or worry, and half of these directly attributed it to fright. In quite a number of instances the history stated that the tremor had developed very shortly after some trauma of the part first exhibiting the tremor.

Dr. Joseph Collins presented an analysis of 50 cases of paralysis agitans. Of this number, 34, or 68 per cent., were males, and 16, or 32 per cent., females. The average age at which the disease developed was 51½ years, the youngest being thirty-two and the oldest seventy-two years old. They were divided according to occupation as follows: Merchants, 7; workmen, 8; laborers, 5; tailors, 4; clerks, 1; clergymen, 1; drivers, 1; carpenters, 1; plasterers, 1; engineers, 2; gardeners, 1; houseworkers, 9; captains, 1; no occupation, 7. The nationalities were: United States, 8; England, 1; Ireland, 16; Germany, 7; Holland, 1; Russia, 6; Austria, 1; not given, 10. The attributed cause was: Worry, in 7 cases; alcohol, 1; excesses, 1; excitement, 1; shock, 1; refrigeration, 1; hard work, 1; pneumonia, 1; grief, 1; bite of cat, 1; unknown, 34. In 7 cases there was a history of injury; in 1 of operation; in 1 of hard work; in 1 of syphilis; while in 40 cases there was no special history of this kind. There was a history of neuropathic heredity in 13 of the cases, of 26 per cent., and a history of paralysis agitans in the parents or uncle in 6 instances. The average duration when first seen was four years, the longest being twenty years and the shortest five months. The part to first show trembling was left upper extremity in 11 cases, left lower extremity in 8, right upper extremity in 15, right lower extremity in 1, upper in 7, lower in 2, right upper and lower in 1, left upper and lower in 1, and all extremities in 4 cases. The initial symptom was: trembling in 24 cases; pain in 11, unsteadiness in 3, numbness in 2, nervousness in 1, stiffness in 1, inactivity of fingers in 1, weakness in 1, loss of power of right hand in 1, headache in 1, and not given in 4 cases. The relation of curvature of the spine was investigated specifically in only the last 20 cases, and was noted in 7 cases. He was convinced that paralysis agitans was a disease of early senility occurring as the reward of virtue.

Dr. M. Allen Starr said that he had had a fairly large experience with paralysis agitans, yet it did not bear out

Dr. Collins' statement about the frequency of the disease among the Celts and its comparative rarity among the Hebrews. He could recall quite a large number of patients among the Jews and a number among the Germans. In hospital and clinic work one was apt to get a one-sided view of such matters because of the large proportion of persons of certain nationalities at such places. Nor did his observations bear out what the last speaker had said about heredity; probably four or five per cent. would represent the proportion showing hereditary influence. Anxiety and trauma appeared to him to bear a distinct relationship. He had never seen a patient absolutely cured of paralysis agitans, but he had observed a very marked improvement in one, and a great variability of symptoms in a number of other cases. The disease did not appear to be a steadily progressive one. He had found that the Swedish massage, skilfully administered, after a prolonged hot bath, gave these patients so much relief that they were willing to keep up such treatment for years. The great majority of his patients had found benefit from hyoscine in doses of 1/100 of a grain, given from two to five times a day.

Dr. Leszynsky said that dispensary and hospital patients were not benefited, but with private patients it was quite different. Four times within the past ten years he had had the opportunity of making the diagnosis very early in the disease. The disease certainly presented remissions at times, and traumatism certainly exerted a distinct influence. Most of these patients were very amenable to suggestion, and in this way could be benefited by treatment. He had not observed good effects from hyoscine except for a very short time, because most of the patients complained of the action of this drug. As systematic exercise had been recommended he had tried the Swoboda system of exercises, which call for voluntary effort entirely, and the patients appeared to be benefited thereby.

Dr. Joseph Fraenkel said that in the past ten years he had seen many cases of paralysis agitans and had witnessed 10 autopsies. It was rare to find a person suffering from paralysis agitans who was gray-haired or old-looking, and the autopsies showed a remarkable freedom from arteriosclerosis. These persons were rarely addicted to the use of alcohol or exhibited evidence of syphilitic infection, and to this extent he would indorse Dr. Collins's statement that this disease was "the reward of virtue." He saw nothing to support the theory that this was a disease of senility. It was common to observe a marked hypertrophy of the skin in these patients. A characteristic feature was the difficulty of stopping the patient when on any one line of thought and change him to another. A pseudonystagmus was often observed. Although the tremor ceased at night, the paralysis agitans patient presented the same attitude in sleep as when awake. He agreed with Dr. Collins that very little could be done for these patients by treatment of any kind.

Dr. Harlow Brooks said that he had only studied four cases of paralysis agitans post mortem, and the findings were so conflicting that he was very skeptical about any lesions claimed to be characteristic of the disease. He was of the opinion that deformity of the spinal column was very common in persons who were not very well developed, basing this opinion upon many observations made in the deadhouse as well as in examining during 1898 the recruits for service in the regular army. He thought that fully 7 out of 50 such recruits would show as much spinal deformity as Dr. Collins's cases, even though these persons were of sufficiently good physique to be accepted in the army.

Dr. Collins said that his statistics with regard to the Celts might be refuted, but to do so the actual figures must be presented and not cases recalled from memory. He believed also that the more paralysis agitans was treated the worse it became.

Dr. Hunt said he understood that the premature senility referred to the nervous system, and not to the arterial tree when used in connection with paralysis agitans.

Dr. Pearce Bailey was of the opinion that two-thirds of the cases of paralysis agitans began after the age of sixty. A disease which could become fairly well developed in the course of a few weeks could hardly be regarded as an organic disease of the nervous system, and he was inclined to think that the evidence was rather in favor of its being a disease of the muscular system, resulting possibly from the action of certain toxins. He believed it was distinctly induced by trauma, either psychic or physical, for there were too many definite and striking clinical records of this kind. The disease usually first appeared in the hands, and yet in cases of injury to the legs the disease was more apt to begin in the legs. A large proportion of the persons coming to Dr. Starr's clinic suffering from paralysis agitans were apparently right-handed workers.

**Specimen of Brain Abscess.**—Dr. Joseph Collins presented this specimen removed from an Italian laborer, forty years old, who had not been sick up to two months before his admission to the City Hospital, since which time he had suffered from headache only. On January 14 he became stuporous. There was no paralysis, paresis or spasm, in fact, no objective symptom other than stupor. Examination on February 3 showed the head to be drawn over to the right side and flexed, and the right upper extremity partly flexed at both joints. There was a peculiar elastic resistance of the right upper extremity on extending it. Knee-jerks were absent. The plantar jerk on the right side was lively, but could not be elicited on the left side. The body temperature remained about normal, and the pulse varied from 68 to 90 and the respirations between 20 and 22. Dr. Collins's diagnosis was circumscribed non-purulent encephalitis, and because of the motor symptoms on the right side it was thought to be in the left cerebral hemisphere. However, the lesion was found to be a focus of comparatively recent yellow softening situated on the right convexity, involving that portion of the first temporal convolution lying immediately below the supramarginal and angular gyri and separated from these by the Sylvian fissure. It involved the posterior arm of the internal capsule, and extended apparently into the extraventricular radiations emanating from the lower third of the posterior central gyrus. The internal capsule was not involved in its passage between the basal ganglia. No thrombus could be found. The special interest of the case lay in the fact that the motor symptoms were on the right side and the lesion was found on the same side.

## OBSTETRICAL SOCIETY OF PHILADELPHIA.

*Stated Meeting, April 2, 1903.*

The President, J. M. Fisher, M.D., in the Chair.

**Treatment of the Common Clinical Forms of Gonorrhea in the Female.**—This paper was read by Dr. R. Oliver Kevin, who deplored the fact that too little attention was given by physicians generally to the study of gonorrhea in the female and as a consequence the disease is comparatively seldom recognized until the woman has communicated the disease to others. The baneful effects of gonorrhea in the female were mentioned and asserted to be more serious than syphilis; as evidence of this were cited many cases of pus tubes, peritonitis, cystitis, abscesses, endometritis, etc., which occasioned much suffering and chronic invalidism. The point especially emphasized was the important rôle

played by the infection of Bartholin's glands in propagating the disease to the male and leading to apparently fresh infections in the woman herself; the cause of this is the extreme frequency of involvement of these glands which break down, forming small sinuses full of gonococci which will escape the observation of physicians unless pains are taken to critically examine the Bartholin glands in every woman presenting herself with symptoms of irritation or inflammation of the parts. The following is a classification as to structures involved: Urethra, cervix vagina, vulva, uterus, rectum and inguinal glands. If the uterus is the seat of an acute gonococcus infection local measures should be avoided owing to the danger of favoring the communication of the disease to the tubes, ovaries and peritoneum. In such cases the patient should be placed in bed and treated on general constitutional principles until the acute stage has subsided, after which injection of one-half ounce of 10 to 20-per-cent. solution of argyrol should be carefully made once daily. In involvement of the urethra, a 5 to 10-per-cent. solution of argyrol should be made 3 or 4 times daily, either by the physician or the patient. The writer stated that since adopting this plan of treatment no involvement of the bladder has been observed in his cases. Should, however, infection of the bladder exist, urinary antiseptics should be administered internally and the bladder be irrigated with weak solutions of silver nitrate, copper sulphate or potassium permanganate, after which one-half ounce of a 20-per-cent. solution of argyrol is injected in the bladder and allowed to remain. When the urethral follicles or Skene's glands are involved, the urethra should be dilated with ordinary sounds lubricated with Fenger's ointment, or, preferably, 20-per-cent. argyrol ointment in lanoline. In some cases the glands are best treated by injection (blunt-pointed hypodermic) with carbolic acid or silver nitrate 20 grains to the ounce.

In gonorrhea of the cervix the parts must be first cleansed of adherent secretions and a few drops of 20-per-cent. argyrol solution or 5-per-cent. protargol injection with a long-nozzled syringe, care being taken to previously expel all air from the syringe to avoid production of uterine colic. Treatment must be made daily. Tampons saturated with 20-per-cent. argyrol solution should be left in contact with the cervix for from 4 to 6 hours in order to obtain the continued gonococcidal effects of the drug.

When the uterus is involved, the organ should be irrigated with any of the following solutions: Creolin, lysol, normal salt solution, potassium permanganate, argyrol, protargol; or a mixture of carbolic acid, sulphocarbolate of zinc and glycerine. After irrigation a strip of gauze saturated with 20-per-cent. argyrol solution should be packed in the uterine cavity and allowed to remain. In some cases after subsidence of the acute stage the cervix and entire vaginal mucous membrane should be painted with silver nitrate solution 10 grains to the ounce. For the catarrhal process that remains no combination equals in efficiency a mixture of ichthyol 25 per cent., argyrol 25 per cent. and glycerin 50 per cent., used freely as a local application every day or two. Uterine curettement is dangerous when gonorrhea exists.

The author summarized his paper as follows: Always make a thorough examination of the region of Bartholin's glands in suspected cases. If these are infected, flush the vagina with antiseptic solutions, make free incision in the sinuses and glands, remove diseased or necrosed tissue with a curette, and swab the entire surface with 50-per-cent. argyrol solution, strong carbolic acid, or nitrate of silver. Argyrol is to be preferred because it is non-irritating and possesses deep penetrative power. Never use local treatment in an acute gonorrhea of the uterus, but put the patient at absolute rest and endeavor thereby to prevent the spread of the disease to the uterine adnexa and peritoneum.

Dr. Maier said he had enjoyed Dr. Kevin's paper very much; although his intra-uterine method of treatment at times startled him. It is in this class of cases that one must proceed with exceeding care or be liable to bring about an exacerbation of the disease. He thinks the tendency of the gonococcic infection is to remain more superficial, the micro-organisms lying in and between the epithelial cells. For this reason the object of their treatment should be to bring about a thorough desquamation of the superficial tissues. Ichthyol lends itself very favorably to this. Lately he had been using a 50-per-cent. formalin solution with marked benefit.

Dr. Oliver Hopkinson said he would like to ask Dr. Kevin what salts of silver he uses, and which he prefers under certain conditions. He has not found much difference in the use of protargol from that of the old nitrate of silver. He would like to know whether Dr. Kevin has found these new salts superior as applications to the old silver salts.

Dr. W. S. Stewart remarked that he had a little experience with gonorrhoea in various forms, particularly in males. His largest experience was during his service in the Civil War. He found his results were very much better when he began with mild treatment. The inflammation resulting from strong caustics was more terrible than the original disease.

Dr. John C. DaCosta said that the younger Gross, who was most successful in treating these cases, used continually to urge common sense in treating them; and himself used a great deal of common sense in his methods. In the primary inflammatory stage he used the mildest possible remedies. Dr. DaCosta has not much confidence in the new salts, believing them to be the preparations of manufacturers who are interested in pushing them. Some possibly use them on the principle of the old doctor's advice to his son: "My son, use new remedies while they are fashionable and while they cure." In the chronic cases he uses the old-fashioned nitrate of silver in solution of not less than 60 grains to the ounce, following the application sometimes by salt solution and finds that one, or sometimes two, applications often cure an old chronic gonorrhea.

Dr. Kevin in closing, said that swabbing out the uterus will not cure if the gonorrhea is not located there. Gonorrhea vaginitis is very rare. He has seen it but a few times in his life. He has had no experience in the use of formalin. Menge reports success with it in chronic cases. Dr. Kevin was afraid to use it in office practice, and if employed in the uterus he would advise that the cervix be first dilated to give good drainage. In chronic cases he has found the use of argyrol and protargol satisfactory, also nitrate of silver, although it is not as penetrating as the silver salts protargol and argyrol. He has had good results from them all used in the cervix. His experience has been that if he was not able to get rid of the purulent tenacious drop at the cervical mouth to go into the uterus with the old-fashioned treatment of tincture of iodine and carbolic acid, when the character of the discharge would soon change for the better and lose its mucopurulent appearance.

**The Electrothermic Angiotribe in the Removal of a Large Suppurative Tubo-ovarian Mass with Resection of Four Inches of Colon and End-to-End Anastomosis.**—This was the subject of Dr. A. J. Downes, of Philadelphia, in which he reported a case of suppurative tubo-ovarian disease forming a mass that completely filled the left side of the pelvis with dense adhesions to surrounding structures including a portion of the descending colon, which after being freed from its surroundings presented a thick, wide pedicle, closely as-

sociated with the uterus. In order to remove this with the least possible danger of contaminating the field of operation by escaping pus the electrothermic angiotribe was applied close to the side of the uterus for forty seconds. Upon removing the mass by section on the outer side of the thermic blade and releasing the instrument it was observed that the stump left by the operation was a well-cooked, and, therefore, sterile, non-oozing ribbon of tissue closely hugging the uterus. The colon stripped of its mesentery and partially denuded of peritoneum to the length of four inches was resected as follows: The bowel was clamped by his three-eighth-inch angiotribe at either extremity of the denuded area and the current turned into the blades for fifty seconds. After removing the blades section was made through the middle line of the ribbons thus formed. With the ends of the bowel thus occluded anastomosis was performed by a triple layer of continuous chromicized catgut sutures without sight of, or contact with, the mucous membrane. With the little finger the bowel was now invaginated at some distance from either side of the site of the operation with a view of breaking through the ribbons and thus re-establishing the caliber of the canal. Gas escaping from one section into the other proved the success of this manipulation. Five actively bleeding points, deep in the pelvis, were controlled by grasping them with the tips of straight forceps heated with his so-called electrotherm. Two heavy bands of torn omentum were hemostased by a one-fourth-inch blade thermic angiotribe in twenty seconds. The abdomen was closed without drainage. On the fifth day the patient had three natural bowel movements. Her recovery thus far has been uninterrupted.

Dr. J. M. Fisher said, in the discussion, that upon Dr. Downes' departure for Europe the patient was left in his charge and it is now twelve days since the operation. There has been an aseptic convalescence from the beginning, and the bowels are moved daily. As indicated in the paper, he assisted Dr. Downes in the operation. The patient presented complications that proved of especial value in the demonstration of the practical utility of his apparatus. The mass removed was closely associated with the uterus, enveloped by densely adherent omentum and the lower portion of the colon, it was firmly bound to the rectum and floor of the pelvis and was enucleated with considerable difficulty. Had the ordinary method of hemostasis been employed the close proximity of the mass to the uterus would have required ligation of the wide pedicle in sections and an incision of the parts through pus-degenerated areas. With this instrument, however, the whole width of the pedicle was grasped, the electric current was applied to the blades for forty seconds, and the whole mass was removed within less than a minute, leaving a well-cooked, sterile, and non-oozing stump that was closely hugging the uterus without a drop of escaping pus to contaminate the field of operation. To him the resection of the colon was a revelation. The intestine partially denuded of peritoneum and stripped of its mesentery to the length of at least four inches, certainly was sufficient to demand resection of this portion of the gut. In doing this he grasped the ends of the section to be removed with the angiotribe and by pressure and the electrothermic method hermetically sealed the lumen of the gut. Cutting through the middle line of the dessicated ribbons thus formed after releasing the instrument, not alone left the ends to be reunited, sealed and sterile, but the closed cooked ends of the portion of gut removed likewise rendered this a negative factor as a possible source of infection. The cooked ribbons of the bowel within the abdomen were now placed one upon the other and the anastomosis effected as described. He now invaginated the intestine from either side of the line of suture and broke through the agglutinated structures and thus re-established the continuity of the canal. At no stage of the operation was it possible for either fecal matter or gas to escape, in fact no portion of the intestinal mucosa was exposed to view. Taken all in all, Dr. Fisher says it was the neatest, and aseptically considered, the cleanest and most perfect piece of bowel surgery he had ever witnessed. He cannot conceive how one could do an intestinal resection with greater safety than by this particular method. Anastomosis was made in much less time and just as effectively as if it had been done by any one of the commonly recognized procedures, minus the possibility of infection from exposure of the lumen of the gut. Recently he read a report of Dr. Keefe, surgeon to one of the hospitals in Providence, R. I., who has done a number of resections with the Downes instrument upon dogs, and in no instance did he consider it necessary to separate the agglutinated ends before closing the abdomen, the continuity of the canal in every case becoming re-established within a few days by sloughing of the inverted ends. The pathological report upon the specimen removed by Dr. Downes has not yet been received. Dr. Fisher believes it to be a suppurating ovarian fibroma.

Dr. Kevin said that he saw Dr. Downes operate on a varicocele by his method with the angiotribe; there followed no complication or stitch abscess and the case recovered more rapidly than is usual in the ordinary open operation. Personally he thinks he would feel more secure in an abdominal operation on himself, to have a good stout ligature on a bleeding abdominal vessel. He also saw Dr. Downes remove the sac of a hydrocele and there was no sloughing or secondary infection, while the recovery was more rapid than usual.

Dr. Nassau said he had seen Dr. Downes use the forceps but once. That was before he developed the angiotribe. Personally he knows nothing of the use of the instrument. It seemed to him that the sealing over temporarily of the ends of the bowel is a very questionable method. In doing end-to-end suture of the intestine it is an important question whether it is not better to put the sutures through the entire coat of the bowel, as suggested by Connell, and tie the last stitch inside, and whether it does not make a better and safer union. He has used that method in one gastro-enterostotomy and been perfectly satisfied regarding the line of union between the intestine and the stomach. The patient, however, died from hemorrhage. If this method of Dr. Downes were used to make end-to-end suture it would be impossible to tie our sutures in the bowel. The Lembert suture does not hold a very great amount of tissue, and unless one is certain to pick up the submucous coat in the suture, one might as well not sew it at all. He believes some of the gentlemen who have studied the question of intestinal anastomosis would think it safer and better to sew the mucous membrane separately, making a row of approximal sutures and over all a line of sealing sutures. If the peritoneum is going to take care of the pus from pus tubes he thinks there is no need to fear a slight amount of infection from the bowel contents during anastomosis. This danger of infection can be eliminated by packing off. He would only be afraid to trust the peritoneum in the appendix cases, though Dr. Morris, of New York, has claimed such nice results. He has seen other gentlemen operate in the same way with great success. In one patient who left the hospital last week a considerable amount of pus was spilled, but the wound was disinfected and closed without drainage. There was little pain, no fever and no suppuration. In a second case the appendix was so plastered over with lymph that dissection was difficult. When it was stripped loose and the adhesions broken up the wound was disinfected, the abdomen closed and

the progress was satisfactory. If in such cases one can take care of infection, why should a method be used that might possibly give insecure stitching and in which there is difficulty in applying the mesenteric portion of the stitch.

Dr. Franklin said that he had seen Dr. Downes operate eight or nine times and had seen the cases afterward and known that the cures were perfect. He seemed to get better results in the inflammatory and pus cases by the use of his forceps than by the ordinary ligature operation. Whether this is due to the fact that he can remove more infected tissue, or that he leaves less raw surface after operation, Dr. Franklin does not know. He has no trouble in controlling hemorrhage. His present method with the angiotribe is much to be preferred to the one used several months ago.

Dr. Maier desired, through Dr. Fisher, to extend his congratulations to Dr. Downes. He had only seen the electrothermic cautery used once. He decided at that time that it was the ideal method of dealing with a pedunculated mass. He wondered how he would proceed in just such a condition as presented by the paper this evening. From the paper and Dr. Fisher's description he thinks he has overcome the difficulty of sessile attachment. There is remaining one other class of cases which he would like to see Dr. Downes deal with; it is those inflammatory conditions in which the structures are so friable that it is only after the most arduous and painstaking care that one is able to control the hemorrhage. If Dr. Downes is able to dessicate this tissue, and thus rapidly stop the bleeding, Dr. Maier will confess it to be, in his judgment, the ideal method. Concerning the bowel surgery, it takes time, and some handling of the ends of the intestines to introduce Lembert sutures; and he confesses he would feel safer with the forceps. There is some difference in a pedicle sealed and dropped back into the pelvic cavity, and the end of a gut temporarily sealed and subject to the subsequent handling required to introduce sutures.

Dr. Fisher, in closing the discussion of Dr. Downes' paper, said he was convinced that the electrothermic angiotribe is one of the coming things in surgery. Dr. Downes has a well-perfected instrument, and does good work. The mass in this particular case could not have been removed with the ligature without the extravasation of pus, but with the use of this instrument it was removed without the escape of anything to contaminate the field. Time is an element in abdominal surgery. The thick, wide pedicle to which he applied the whole length of the blades was thoroughly cooked within forty seconds and the mass removed; and the stump that was left was necessarily aseptic, and from the homogeneous appearance of the compressed structure he felt confident that there was no danger of hemorrhage. As indicated by Dr. Nassau, he has improved his instrument very materially in the last few months, and has combined the principle of the angiotribe with that of the cooking process first introduced by Dr. Skene. Dr. Skene's instrument was cumbersome; it could not be boiled; the blades could not be kept cool while in use; and three to four minutes were required to cook the structures. As already indicated, Dr. Keefe has done a number of operations with the Downes apparatus with uniform success and those upon the intestines of dogs are worthy of especial consideration by surgeons, and should prove of some interest to the friends of antivivisection. Even though the peritoneum, as has been suggested, will at times tolerate and dispose of small quantities of pus and fecal matter it is a danger to be avoided nevertheless; the object of all in abdominal work is to attain as near as possible the ideal, aseptically. If an intestinal anastomosis can be done without difficulty and without exposing the lining membrane of the bowel, and within one-quarter of the time usually expended in such work, he thinks it a common-sense proposition for us to adopt the plan that offers these advantages. It is interesting to note that those who have gained sufficient familiarity with the use of the instrument consider it indispensable in their work. The objection has been urged that owing to the absence of the electric current in private houses the use of the instrument is necessarily limited; in answering this we might say that abdominal operations at this advanced day are usually performed in hospitals, and of these but few, even in the smaller towns, are unprovided with an electric outfit to secure the necessary current.

---

## PHILADELPHIA ACADEMY OF SURGERY.

*Stated Meeting, held May 11, 1903.*

The President, Richard H. Harte, M.D., in the Chair.

**Operations Upon the Stomach and First Portion of the Duodenum.**—This paper was read by Dr. William J. Mayo, of Rochester, Minn., in which he reviewed 303 operations, 286 of which were taken from the records of St. Mary's Hospital, Rochester, Minn., and 17 from the Minnesota State Hospital for the Insane at Rochester and St. Peter. The average age of the patients was forty-two years, 42 per cent. being males and 58 per cent. females. There were 26 cases of duodenal ulcer with two deaths. Lesions in the first portion of the duodenum cannot be easily differentiated from lesions in the stomach, which are due to the same causes. He divided lesions in the first portion of the duodenum into two groups, first, those caused by ulcer; and, second, those associated with gall-bladder disease. Of the ulcers limited to the duodenum, there was 1 acute perforating, 2 chronic perforating, 5 active and 3 cicatricial contractions with obstructive symptoms. Two deaths occurred, one from pneumonia and the other from exhaustion following gastro-enterostomy. Several of the cases could not be distinguished from gall-stones until the operation, which was begun for that purpose, and which condition was frequently associated with it. In three cases the gall-bladder was completely separated functionally from the bile tract: in four cases there were crippling adhesions to the gall-bladder, but without stone or cholecystitis, requiring dissection to loosen. The differentiating features in these cases were good appetite, delayed pain, general absence of vomiting, and only in one case, and in that on only one occasion was there hematemesis. The author expressed the opinion that surgical disease of the duodenum was much more frequent than has been supposed.

**Diseases of the Stomach.**—He divided these into two classes: (1) Gastric ulcer and associated causes of serious disturbance; (2) Cancer of the stomach. Out of the 303 cases reported in this paper 277 involved the stomach, with 28 deaths, or 10.1 per cent., 168 of these cases were in the benign group, with 11 deaths. These cases included all the non-malignant obstructions or conditions calling for operation for gastric pain, with or without acute exacerbation. In the majority of the cases the perverted stomach secretions seemed to be the most important cause, which is shown by the almost constant association of excessive secretions with gastric ulcer. Also in that part of the duodenum not protected by alkaline juices the same ulcers have also occurred after jejunostomy has been performed for the purpose of drainage. Drainage to relieve the excessive amount of secretion and thus produce healing of the ulcer is of great importance.

The following classification of gastric ulcer was made: (1) Round ulcer, (*a*) acute; (*b*) chronic. They

have the definite feature that there is but little thickening about the base of the ulcer; (2) Mucous erosions, a condition which must be accepted with caution; (3) Chronic ulcer with thickened base and usually irregular in form; (4) Benign obstruction without regard to cause, although usually of benign origin.

The last two classes are the ones which most frequently call for operation, chronic ulcer being usually found in adults and is more frequent in females. Spasm of the pylorus was thought to be one of the most important causes of the retention of excessive gastric secretion. There were 109 cases of cancer of the stomach, with 17 deaths, or 15.6 per cent. Late diagnosis and cachexia makes the report of this group rather discouraging, most of the operations were of a palliative character. Early exploratory incision in suspected cases was recommended, and all the vascular and lymphatic connections with the diseased area should be removed. He then gave a full description of the method he employed in doing the operation. The period without recurrence after the operation has been varied, one case having gone two years and another three years and six months. He then discussed the three methods of improving stomach drainage, *i.e.*, pyloroplasty; gastro-enterostomy and gastroduodenostomy.

**Difficulty of Diagnosis.**—Dr. Albert Vander Veer, of Albany, N. Y., referred to the difficulty of diagnosing conditions in the lower third of the stomach and the upper third of the duodenum, referring to two cases in which he thought he had to deal with gastric ulcer, in which operation proved it to be duodenal ulcer. In cases where all the symptoms seemed to point very strongly to an ulcer in the stomach and none was revealed upon opening the organ, he believed it could sometimes be discovered by lifting out the organ and holding it up to the light. The difficulty of differentiating between carcinoma and ulcer, when the growth occured in the posterior wall of the stomach was commented upon; gastro-enterostomy was thought to be the preferable operation for such conditions. He felt that many of the cases were left too long solely under the treatment of the medical man, and that if the clinical history and examination of the patient do not reveal clearly the conditions present, recommended exploratory operation. If possible, the complete operation should be done, but if the condition of the patient is such as to contra-indicate this, much relief can be obtained by a gastro-enterostomy. In regard to shortening of the ligaments for their treatment of gastroptosis, while he had had very little experience with this method, he felt that better results would be obtained by gastro-enterostomy with the establishment of good drainage. In regard to the pyloroplastic operation, he stated that he had in some instances gotten very good results and in other instances the symptoms recurred, which he thought was probably due to the fact that the operation was too high up, and attributed Dr. Finney's success with this method to the fact that he made the outlet lower down.

**Gastro-enterostomy Instead of Pyloroplasty.**—Dr. B. G. A. Moynihan, of Leeds, England, felt that the operation of pyloroplasty could be practically abandoned, he having done the operation three times, and in only one of the three cases did it prove satisfactory, in the third case a gastro-enterostomy being performed three or four months after the original operation. He did not feel that the operation was in any particular as satisfactory as the operation of gastro-enterostomy, stating that he had operated upon 75 cases by the latter method with only one death. He stated that he had not used the Murphy button in the last 65 cases, as he believed the simple suture was preferable, but stated that in the employment of the Murphy button in the first of his cases, he had noticed that it destroyed a considerable portion of the mucous membrane around the union which he considered of very great importance, and which he had been doing in all his operations. By the method which he has employed the section of the stomach and the section of the jejunum where the anastomosis is to be made are each grasped in a pair of forceps and brought outside of the abdomen, and the continuous suture applied. In regard to malignant disease of the stomach he believed that the infection took place principally through the lymphatic system, and in the operation therefor, he believed that first the greater curvature and then the lesser curvature should be removed. In regard to duodenal ulcer he believed that there were but very few cases in which this was a primary condition, feeling that in the majority of cases there had been a precedent gastric ulcer. Gastric ulcer is so frequently multiple that he did not believe excision thereof to be practicable, as future trouble may result from a remaining undiscovered ulcer, and searching for the ulcer materially affects the operation of gastro-enterostomy.

**Early Operation Imperative.**—Dr. J. B. Murphy, of Chicago, referred to the fact that the great majority of all cases of carcinoma occur in the pyloric end of the stomach, and as the first set of glands becomes involved by gravity are the lymphatic glands, any operation which is expected to produce permanent results must look to the removal of these glands, early operation being imperative. He further referred to the fact that about 10 per cent. of all cases of gastric carcinoma occurred in the cardiac end of the stomach and are practically unamenable to treatment. He referred to the fact that the surgeon usually sees the cases of gastric disease in the following numerical order: (1) Gastric carcinoma, (2) gastric ulcer, (3) pyloric stenosis, and (4) pyloric retention. As the gastric carcinoma is usually a sequence of the other conditions, he felt that in order to obtain the best results by operative treatment, the order in which these cases were seen should be the reverse. He believed that in order for the operation of pylorectomy, to attain the best possible results, it was necessary that it should be done early. He referred to the fact that the cases of gastroptosis are treated erroneously by the medical man by washing out the stomach and reducing the amount of food, on the theory that the condition is due to a weakening of the wall of the stomach, whereas, as has been definitely demonstrated by Dr. Mayo, it is due to a mechanical condition at the pylorus. He felt that the all-important factor in the operation was to secure permanent drainage of the most dependent portion of the stomach, and the only operation which had been used a sufficient length of time to justify the statement that it was the best, he felt, was gastro-enterostomy. He felt that if pyloroplasty was going to be of benefit to the patients it must be done early, in order to avoid ulceration and changes in the gastric secretions which lead on to malignant disease. He also expressed the opinion that so soon as it became demonstrated to the physician that surgical operations were safe and afforded great relief, the cases should be sent to the surgeon much earlier.

Dr. J. M. T. Finney, of Baltimore, Md., confined his remarks to the consideration of the question of pyloric stenosis of benign origin, and believed that the main question was thorough drainage, and any method that would produce this result he felt would be satisfactory. He referred to the fact that the advocates of gastro-enterostomy were far in excess of those who recommended pyloroplasty at the present time, which he believed to be due largely to the fact that the operation had not been properly performed. He felt that much better results could be obtained by the conjunctive work of the physician and surgeon in these cases, not necessarily with a view to immediate operation, but for the purpose

of ascertaining the exact conditions present. He advocated early exploratory operation under cocaine. He felt that pyloroplasty was preferable to gastrojejunostomy from the fact that it makes the pylorus in a more normal position. The mortality in pylorectomy he felt was too high to justify its employment except in cases of pyloric cancer. He stated that he had employed the method as described by Hartman in eight case of pyloric cancer, each of which made good recoveries and lived varying lengths of time. Owing to the nature of the growth, however, and the necessary involvement of the lymphatic structures, he felt that it was practically impossible to eradicate entirely the cancerous growth, and that recurrence would take place in a great many instances, for which reason he felt that the method advocated by Dr. Mayo, of direct anastomosis of the lower end of the stomach to the duodenum would probably produce the best results. He felt that the operation of gastro-enterostomy had not been followed in all cases by the results claimed for it by some of the previous speakers, among the untoward effects frequently noted being the vicious circle and symptoms of pyloric obstruction due to the fact that the outlet was made too high up in the stomach.

Dr. J. Chalmers DaCosta commended the Academy on their good fortune in having had the opportunity of listening to such great workers in this line as Drs. Mayo, Vander Veer, Moynihan, Murphy, Finney, and Mikulicz-Radecki, and his appreciation of their courtesy in having participated in the papers and the discussions.

## BOOK REVIEWS.

ANATOMY OF THE BRAIN AND SPINAL CORD. WITH SPECIAL REFERENCE TO THE GROUPING AND CHANGING OF NEURONS INTO CONDUCTION PATHS. By HARRY E. SANTEE, M.D., Ph.D., Professor of Anatomy in the College of Physicians and Surgeons, University of Illinois; Professor of Anatomy in the Harvey Medical College, Chicago. Third edition. E. H. Colegrove, Chicago.

THE present volume is a convenient short description in 200 odd pages of the structure and anatomy of the nervous system. It is meant to serve the purpose of a laboratory manual and as such is to be commended very highly. As a text-book, however, for the general reader, it is of little service, being practically non-illustrated. For students, therefore, we can most heartily recommend it. For practitioners, however, unless they are actually doing dissections or have an accompanying atlas it will be found of secondary service only.

The author has compressed in very short compass a great deal of useful and well-ordered information. It, therefore, makes a very desirable small book of reference.

DISEASES OF THE STOMACH. By MAX EINHORN, M.D., Professor in Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Dispensary. Third revised edition. William Wood & Company, New York.

AS AN authority on stomach diseases and as an ingenious inventor of diagnostic implements, Professor Einhorn is known the world over; it therefore is not surprising to find his book a practical and suggestive treatise on stomach affections. Rather too much space has been devoted to detailed descriptions of gastric sprays, stomach buckets, esophagoscopes and other instruments, yet the author, without sacrifice of clearness, has succeeded in keeping the book of reasonable size.

Besides the usual chapters on anatomy, physiology, diet, methods of examination, etc., the author divides the book into sections on Organic Diseases with constant lesions, Functional Diseases with variable lesions, abnormal size, shape and position, Nervous Affections, and Condition of Stomach in diseases of other organs. A valuable description is that of enteroptosis or Glénard's disease. We would suggest that such diseases as "Gastrosuccorrhea continua periodica," "Achylia gastrica," and "Ischochymia" be referred to by their English names; as we prefer "cancer of the stomach" to "carcinoma ventriculi."

No mention is made of Pawlow's valuable work on the digestive glands, nor of much recent work which is still the subject of controversy, though the numerous references show a wide range of reading.

A TEXT-BOOK OF LEGAL MEDICINE AND TOXICOLOGY. Edited by FREDERICK PETERSON, M.D., President of the New York Sate Commission in Lunacy, and WALTER S. HAINES, M.D., Professor of Chemistry, Pharmacy, and Toxicology in Rush Medical College. In two volumes. Vol. I. W. B. Saunders & Co., New York, Philadelphia, and London.

THIS first volume of Peterson and Haines Legal Text-Book comes at a time when works of this class are very much in demand. There has been nothing authoritative published in this country on this subject of recent years that is in any sense of the word up-to-date and modern, and the present volume, therefore, fits a need that is real and pressing. It not only fits a need from the standpoint of timeliness, but also sets a standard of what a text-book on toxicology and legal medicine should be.

It is a very large work, even if this first volume alone is taken into consideration and the chapters are all of practical interest to all types of medical men, not only neurologists and alienists but the general practitioner, surgeons and anyone having to do with the care or treatment of the sick.

From the illustrative point of view, the work is an exemplary one and we know of no other work along these lines that is more deserving of high commendation than the present one and we await the second volume dealing with toxicology with interest, trusting to be able to make a full analysis of the entire work on its appearance.

BACTERIA IN MILK AND ITS PRODUCTS. By H. R. CONN, Ph.D., Wesleyan University. P. Blakiston's Son & Co., Philadelphia.

NO MORE significant chapter in the history of modern science can be found than that dealing with the relationship of bacteria to agricultural processes, and in no single one of these processes is the story complete and more interesting than that dealing with dairying. In fact, successful dairying at the present time depends to a very large extent upon skill in handling bacteria, and no scientific cheese maker or butter manufacturer can meet the present conditions of supply in this and other enlightened communities without a knowledge of these microscopical organisms. Therefore, in every school of dairying and in every agricultural college, the study of bacteria has become a necessary part of the curriculum.

The present volume is intended to meet just this want. It is a short, popular and yet complete description of the various bacteria which are found in milk and a thorough discussion of the relationship of changes wrought in milk and milk products by bacterial enzymatic action.

It is written in the author's well-known and commendable style and is a book that can be read to advantage

by every physician, both in the city and in the country, since a knowledge of the changes that take place in milk are so essential in dietetics.

Physical Chemistry for Physicians and Biologists. By Dr. Ernst Cohen. Translated by Martin H. Fischer, M.D., Instructor in Physiology in the University of California. Henry Hall & Co.

The developments of modern chemistry have, during the last decade been very markedly influenced by the teachings of Nernst and Ostwald, pioneers in the study of physical chemistry. Indeed so extensive have been the additions made, the alterations brought about and the new vantage points gained by this young science that the biological sciences have in their turn come under its sway. Indeed the science of physical chemistry has been necessary to explain many of the indirect life phenomena, so far as any theories, non-vitalistic or otherwise, can ever explain such phenomena.

The present series of lectures make a very excellent introduction to the study of physical chemistry and it can be most heartily commended to the medical profession.

There is, perhaps, a little too much mathematics for the average man, but mathematics are unfortunately essential to the understanding of molecular physics. The mathematics, however, in the present volume have been reduced to a minimum, making it one of the most serviceable of recent additions to this growing branch of science.

Bacteriology. A Manual for Students and Practitioners. By Fred. C. Zapffe, M.D., Professor of Pathology and Bacteriology in the Illinois Medical College; Professor of Histology in the Department of Medicine and in the School of Dentistry of the University of Illinois, Chicago. Series edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York; Visiting Surgeon, Bellevue Hospital, New York. Illustrated with 146 engravings and 7 colored plates. Lea Brothers & Co., Philadelphia and New York.

Another volume of Lea's Series of Pocket Textbooks has recently been published and fully maintains the high standard set by the previously appearing volumes of this convenient series. The book has been written especially to fulfill the needs of the student, all unnecessary scientific discussions having been excluded, but the general practitioner will find it a very handy reference book upon the subject, for it contains not only a full and comprehensive treatment of the subject itself but also particular attention has been given to its practical relation to medicine. The illustrations and plates are numerous and have evidently been prepared with considerable care, for they well serve the purpose of explanation and elucidation. The laboratory methods are given in sufficient detail to be of service to the student and the material is complete enough to serve the purpose of any class-room work.

System of Physiologic Therapeutics. Edited by S. S. Cohen, A.M., M.D. Vol. X. Pneumotherapy Including Ærotherapy and Inhalation Methods and Therapy. By Dr. P. L. Tissier, Assisting Consultant Physician to Laennec and Lariboisiere Hospital, Chief-of-Clinic in the Faculty of Medicine of the University of Paris. P. Blakiston's Son & Co., Philadelphia.

This is a further contribution to the System of Physiologic Therapeutics outlined by Dr. Cohen and the present volume makes a very worthy addition to the system. The work is divided into two parts, Part I on Ærotherapy and Part II on Inhalation Methods and Therapy. Air as a therapeutic agent had been utilized from very ancient times, but exactness in methods of limitation and clearly defined lines of therapy have been wanting until comparatively recent times.

The author here gives a short summary and then plunges into the physiological relations of the atmosphere, its position and character to respiration. This is all discussed in 36 pages, hence it can be readily seen that this therapeutical portion of it is compressed. Open-air treatment of tuberculosis naturally comes in for a large share of the author's descriptions.

Special chapters on artificial pneumotherapy, compressed air, both high atmospheric pressure, pneumatic chambers, etc., are well considered, the book being rich from the standpoint of procedure and apparatus particularly.

In Part II the various methods of inhalation by which air charged with medicinal substances is introduced into the air passages is considered at great length.

The book is an extremely practical one and whereas, in places, perhaps a trifle optimistic in its teachings concerning the value of the various methods employed, is one whose facts should be in the possession of every practitioner.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Dr. H. A. Hare and H. R. M. Landis. Vol. II, June, 1903. Lea Brothers & Co., New York and Philadelphia.

This present volume contains the report of progress on the surgery of the abdomen, advances in the field of gynecology, new researches on diseases of the blood, ductless glands, the hemorrhagic diseases and diseases of metabolism and an article on ophthalmology. These are contributed by Drs. W. B. Coley, John G. Clark, Alfred Stengel, and Edward Jackson.

The same high praise that it has been our privilege and pleasure to accord to Progressive Medicine in the past is its due in the present number. We have rarely seen so valuable a work that has kept its high standard for so long a time, and, from the evident mutual understanding of editor and contributors, there is little reason to believe that Progressive Medicine will ever sink into second rank, but will always remain a leader in this type of work.

## BOOKS RECEIVED.

*The* Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Surgical Asepsis. By Dr. H. B. Palmer. 8vo, 231 pages. Illustrated. F. A. Davis Co., Philadelphia.

A Text-Book of Chemistry. By Dr. E. C. Hill. 8vo, 523 pages. Illustrated. F. A. Davis Co., Philadelphia.

Studies in the Psychology of Sex. By Dr. Haverlock Ellis. 8vo, 266 pages. E. A. Davis Co., Philadelphia.

Progressive Medicine. Vol. II. June 1903. 8vo, 435 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Syphilis in Dentistry. By Drs. L. B. Baldwin and E. R. Larned. 8vo, 120 pages. Illustrated. E. H. Colegrove, Chicago.

Diseases of the Pancreas. By Dr. E. L. Opie. 8vo, 360 pages. Illustrated. J. B. Lippincott Co., Philadelphia and London.

## ORIGINAL ARTICLES.

### STUDIES ON THE ACTION OF ALCOHOL IN DISEASE, ESPECIALLY UPON THE CIRCULATION.*

BY RICHARD C. CABOT, M.D.,
of Boston, Mass.

PERHAPS no subject has been more frequently or more heatedly discussed during the last few years than the action and value of alcohol. We have had two interesting symposia upon the subject in Boston within a year, and many similar discussions are reported in domestic and foreign journals. One might think, therefore, that the subject was about threshed out and that nothing new could be said about it, but as one looks over the reports of these discussions one fact is very striking, and that is the scarcity of experimental evidence regarding the action of alcohol in diseased human beings.

In the discussions to which I have referred, the disputants have usually ranged themselves in two parties, those favoring the use of alcohol on one side and those opposed to its use on the other. Those who favor its use usually do so on the ground of their general impression that it has done good in cases under their observation. Those opposed to the use of alcohol usually refer to a number of experiments, for the most part not very recent ones, upon the action of the drug in the lower animals. But very rarely has any one anything to say about experiments or measurements of the action of the drug upon any of the functions of the diseased human being. The "advocates of alcohol" say that it does good, but if you ask them: *What* good does it do? Does it decrease temperature? Does it improve sleep? Does it slow or strengthen the heart's action, and if so how much?—they have rarely anything to answer. On the other hand, if you ask the "opponents of alcohol" what harm it does, they will point to the effect produced on a dog or a rabbit by doses of alcohol which would correspond to giving a man a quart of whisky at a drink, or they will refer you to experiments on healthy soldiers or typesetters. The use of such evidence assumes that alcohol acts in the same way in all animals, whereas we know well that its action in mammals is very different from its action in birds, and have by no means proved what is true of its action in dogs or rabbits is true of its use in man. Another common assumption is that the effects of alcohol in disease are similar to its effects in health. But this is a totally unproved assumption, and there is, I think, a good deal of evidence that it is not true.

It seems to me, therefore, that there is a real need for exact, experimental evidence regarding the action of alcohol in sickness, and it is to this problem that I have addressed myself. I have not sought to show that alcohol does good or that it does harm. I have rather tried to find out *what it does*, what its effect is upon temperature, upon the heart and pulse, upon the rapidity of the respiration, upon the amount of urine, upon the sweat, upon the appearance of the tongue, upon the appetite and upon the cerebral condition of the patient as shown in the amount he sleeps, in the effect of the drug upon delirium, and upon his spirits so far as could be ascertained by talking with him.

I will not deny that I have approached the subject with a marked bias, but I hasten to add that I have done all I could to prevent this bias from influencing my observations. That I have succeeded, at least to some extent, is evidenced, I think, by the fact that my results have not come out at all as I expected and indeed hoped that they would.

In order to counteract so far as possible the bad effects of my prejudices, I have recorded each of my observations on separate slips of paper without allowing myself to refer to the chart in which they were later recorded. As I could not retain in memory the records of the individual patients, and did not allow myself to be reminded of them by looking in the chart, I was thus unable to influence the readings in the direction of my expectations, as I previously found it very tempting to do.

In the study of the effects of alcohol on temperature, appetite, sleep, etc., I have circumvented my bias by getting nurses, who had no idea of what I had in mind, to record the data for me on blanks provided for the purpose.

I have said that there was a dearth of experimental evidence regarding the action of alcohol in diseased persons, but this lack is much more striking in certain directions than in others. Certain points have, I think, been pretty well cleared up, while others are still obscure. Hence it may not be out of place to sum up what may be regarded as relatively settled, in order that the unexplored regions may be made more evident by contrast.

About the food value and the digestive action of alcohol, about its effect on temperature, respiration, the secretions and the susceptibility of the lower animals to infection, there is a good deal that we may consider settled.

On the other hand, there are very few experiments upon its action on the *circulation* of the sick, or upon the protective powers of the human blood against infection.

These two problems, then, confront us:

(1) What effect has alcohol upon the circulation in sick persons?

* Read before the Association of American Physicians, May 13, 1903.

(2) What is its effect on the power of man's blood to protect his organism against infection?

The first of these two questions I have tried to answer in the present lecture. The second I hope to attack later.

Before presenting the results of my own experiments I will endeavor to summarize what seems to me established as the result of work previous to my own.

We may treat as established the following statements:

### I. ALCOHOL AND METABOLISM.

(1) In healthy persons alcohol is capable of replacing satisfactorily the fats and carbohydrates of ordinary food.

(2) It is not yet settled whether or not alcohol can replace the proteids of our customary diet.

(3) The food value of alcohol as a substitute for carbohydrates and fat is perfectly consistent with its toxic properties. It is beyond doubt both a food and a poison.

### II. THE ACTION OF ALCOHOL ON DIGESTION AND ABSORPTION.

(4) While it is in the stomach alcohol disturbs the digestive processes to a greater or less extent according to its concentration.

After absorption (either from the stomach or from the intestines) alcohol acts upon the stomach through the nervous system, and exerts a favorable influence both on its secretions and on its motility. But the nervous system is soon blunted to its influence, so that more and more is needed to influence digestion.

(5) On the intestinal absorption of food alcohol has no considerable influence so far as is known.

### III. ALCOHOL AND DIURESIS.

(6) In healthy persons and in renal or cardiac disease, alcohol has no considerable effect as a diuretic. The free diuresis often seen after beer drinking is due in part to the water ingested and in part to the $CO_2$ and other non-alcoholic constituents of the beer.

### IV. ALCOHOL AND DIAPHORESIS.

(7) The experimental data are not conclusive, and great individual differences exist, but the majority of experiments seem to show that alcohol diminishes sweating in healthy persons.

### V. ALCOHOL AND RESPIRATION.

(8) Practically all experiments show that under the influence of alcohol a larger volume of air passes through the lungs. This is especially marked in fatigued persons. There is, however, no increase in the amount of $O_2$ absorbed or in the amount of $CO_2$ given off.

The patient is made to do more work in breathing without getting any known benefit from it.

### ALCOHOL AND PULSE RATE.

Lichtenfels and Frohlich[1] found first a decrease, later an increase in pulse rate.

Tscheschichin[2] and Ruge[3] noted a very marked rise in pulse.

Zimmerberg[4] could find no variation from normal. Reiss got similar results.

Mertens[5] noted no change, Martins[6] a decrease, Jacobi,[7] Duchek,[8] Hemmeter[9] no increase.

In all the experiments in which subjects have been put into an unchanging environment and conditions, the changes in pulse before and after alcohol sink to a minimum.

Wendelstedt[10] took especial pains that the persons on whom he experimented should remain quiet some time before the beginning of the test and stay in just the same position after swallowing the alcohol. With these precautions the changes in pulse rate were trifling. For a few beats the pulse rate sometimes rose a little, but soon returned to normal. Occasionally there was a slight decrease in rate. The following data may be quoted.

N. K., healthy, fasting, horizontal position for two hours before the experiment.

| | | |
|---|---|---|
| I. | 9.30 A.M. | Pulse 54 |
| | 9.50 | " 56 |
| | 10.07 | Sherry, 300 c.c. (=10℥) |
| | 10.15 | Pulse 56 |
| | 10.40 | " 56 |
| | 11.05 | " 56 |
| II. | Same subject; same conditions. | |
| | 8.55 A.M. | Pulse 60 |
| | 9.15 | " 60 |
| | 9.30 | Brandy, 100 c.c. (3½℥) |
| | 9.40 | Pulse 57 |
| | 10.00 | " 58 |
| | 10.20 | " 58 |
| | 10.40 | " 55 |
| | 11.00 | " 60 |

III. Same subject after a hard day's work, and one-half hour in horizontal position.

| | |
|---|---|
| 6.40 P.M. | Pulse 64 |
| 6.55 | Absolute alcohol ℥ ii diluted |
| 7.05 | Pulse 64 (subject drunk) |
| 7.28 | " 64 |
| 7.55 | " 68 |
| 8.15 | " 64 (less drunk) |
| 8.35 | " 68 |

To the finger the pulse after alcohol feels fuller and stronger, and the sphygmograph shows a tracting like the "pulsus celer" of aortic regurgitation.

### BLOOD PRESSURE AFTER ALCOHOL.

Zimmerberg[11] found after putting alcohol into a cat's stomach a marked fall in blood pressure.

Gutnikow[12] experimented on curarized dogs, into whose stomachs he introduced 250 c.c. of 50 per cent. alcohol. The result was a considerable fall in blood pressure together with a dilatation of the small arteries, capillaries, especially in the territory of the splanchnic.

The dog here used was so small (20 kilos), and the dose so enormous, that no inferences ought to be made from these experiments as to the effect of moderate doses in man.

Weissenfeld[13] reports work done in Binz's laboratory. The experiments were carried out on men with the help of v. Basch's sphygmoma-

nometer. After 2 or 3 oz. of sherry the pulse rose in three cases from 15 to 30 mm. Hg.; in one even as much as 60 m.m. Hg.

Passler[14] and Schule.[15] working with Gaertner's tonometer on a healthy man, recorded a fall from 110 to 95 mm. Hg. twenty minutes after sherry and brandy. An hour later the pressure was 115 again.

Rosenfeld[16] worked with dogs, connecting the femoral artery with a mercury manometer. He was careful to avoid the common mistakes of overdosage and overconcentration in the alcoholic solutions used, which were of 10 to 25 per cent. strength, and introduced by a tube into the dog's stomach.

The question whether dogs tolerate alcohol better than men seems to be answered in part by the following facts:

(1) It takes the same dose *per kilo* to narcotize an average man or an average dog.

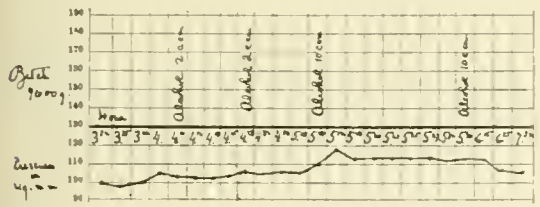

CHART I.—Blood pressures in dogs after alcohol. (Rosenfeld.)

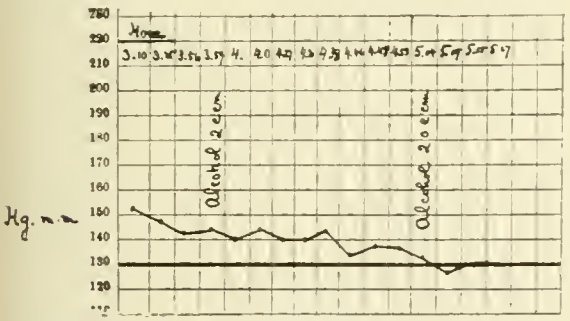

CHART II.—Blood pressures in dogs after alcohol. (Rosenfeld.)

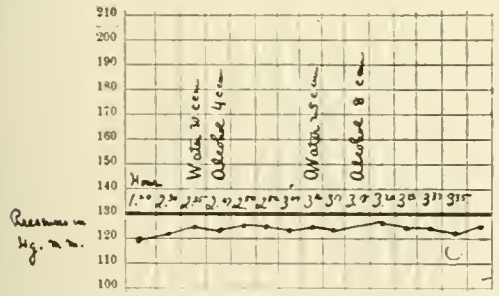

CHART III.—Blood pressure in dog after alcohol.

(2) It takes approximately the same dose *per kilo* to kill a man or a dog.

But to make sure that he did not err on the side of too small dosage Rosenfeld increased his doses from the equivalent of ℥i of whisky at a time up to the equivalent of ℥x of whisky.[17]

The upshot of his 300 or more measurements in 8 dogs was that alcohol has no appreciable effect upon the dog's blood pressure. He used fresh dogs with high blood pressure (152 mm. Hg.), tired dogs with low pressure (82 mm. Hg.) and dogs with pressures intermediate.

The result was the same in all cases. Variations in the pressure from hour to hour were no greater than occurred spontaneously, that is, when no alcohol was given.

### ALCOHOL AND TEMPERATURE.

In states of profound intoxication, belonging practically to the class of collapse states, there may be a very marked lowering of temperature. Experimentally Rosenfeld produced readings of 88.7 F. in dogs.

Therapeutic doses of alcohol given to sound men seemed to produce a slight lowering, amounting, according to the experiments of Binz's pupils, to about .7° F. In sick people the decrease was about the same. The temperature of the skin is greater than that of the rectum, a fact which seems to indicate that the lowering of the rectal temperature and presumably of that of the internal organs in general is due to the dilatation of the cutaneous vessels.

Dumouly[18] found that no effect was produced in fever patients by doses of less than 20 gm. of absolute alcohol (= about ℥iss of whisky).

### ALCOHOL AND THE NEUROMUSCULAR SYSTEM.

The most recent and careful researches on this much-disputed point seem to show that in fresh healthy men the power of voluntary muscular movement is increased about 7 per cent. for the first one-half hour, after which there is decrease to a point about 5 per cent. below the normal.

By diminishing the sense of fatigue, alcohol undoubtedly enables men to push themselves for a short time beyond the limit which nature would otherwise have imposed upon them through fatigue.

### ALCOHOL AND THE SUSCEPTIBILITY TO INFECTION.

Latinen found a decrease in the number of leucocytes in cases of pneumonia during alcoholic medication, and Massart and Bordet observed a negative chemotactic effect upon leucocyte even with very dilute solutions of alcohol.

That it increases in animals the susceptibility to infection and diminishes the animal's power of resistance has been shown so many times and in so many ways that it is not necessary to go over the evidence in detail.

In man something more or less akin to experimental evidence in this matter is furnished by the well-established fact that alcoholics are predisposed to infectious diseases, and have them in a very virulent form.

More direct and important evidence is furnished by researches designed to investigate the antitoxic power of the blood in health and in disease with and without alcohol.

Mircoli[19] compared the antitoxic power of normal human blood with that of alcoholics, by test-

ing the power of each to neutralize Maragliano's tuberculin. The blood of normal men was found to neutralize large doses of this toxin; for example, 10 c.c. of this tuberculin is a fatal dose for animals of 1 kilo weight. But this animal can be protected against this dose by the injection of 2 to 3 c.c. of normal human serum. The serum of chronic invalids, on the other hand, does not possess this power.

But the serum of drunkards was found to be much more more strongly antitoxic than that of normal men. In one case one-tenth of a c.c. of drunkard's serum was sufficient to protect a kilo animal against 10 c.c. of tuberculin. From these facts Mircoli concludes that alcohol is a most valuable remedy for tuberculosis, forgetting that tuberculin and tuberculosis are by no means the same, and that alcoholic cirrhosis and tuberculosis of the lungs or peritoneum are very frequently associated.

Nevertheless, Mircoli's results are of great interest both in themselves and as an indication of the direction in which future research should be turned.

More recently Abbott and Bergey[20] have undertaken a study of the blood reactions of normal and alcoholized rabbits by Ehrlich's methods. Their conclusions are: (1) The daily administration of alcohol per os to rabbits reduces the amount of hemolytic complement in their blood. (2) The diminished reactivating power of the blood of alcoholized rabbits is not due to the presence of small amounts of alcohol as such in the blood. (3) Alcohol not only reduces the amount of complement in the rabbit's blood, but may cause at the same time a reduction in the number of free specific receptors in the blood of a rabbit artificially immunized against an alien blood. (4) The diminished complement-content of the blood of alcoholized rabbits renders the animal more susceptible to the toxic action of an alien blood.

### TOLERANCE OF FEBRILE PATIENTS FOR ALCOHOL.

It must have forced itself upon the notice of any one who has watched the effects of alcohol in fever cases, that such patients will stand an extraordinary amount of the drug without any signs of intoxication.

For example, I recently watched a patient with typhoid in the service of Dr. F. C. Shattuck, who took for nearly a fortnight two ounces of whisky every hour, day and night, that is, three pints of whisky every twenty-four hours, without any sign of intoxication. In the same service a young girl also suffering from typhoid took 60 ounces of champagne; nearly two quarts every day for three weeks without any of the ordinary evidences of intoxication.

This certainly proves that alcohol acts differently in disease and in health, and makes it obvious that the results of experiments with alcohol on healthy men should not be supposed to prove what its effects in sickness may be.

But because alcohol acts *differently* in disease, are we obliged to suppose that it acts *more beneficially* than in health?

That we do not smell it in the breath of typhoid fever patients, despite a dosage which would make a well person reek with it, does not point to any considerable difference in the amount burned up in the body, for even in the intoxicated states produced by alcohol in healthy persons, 98 per cent. of the alcohol is burned in the body. The alcoholic odor in the breath does not prove that any considerable portion of the alcohol is being excreted through the lungs.

Alcohol given to dogs with sugar does not make them nearly as drunk as when it is given without sugar,[21] but its harmful effects are no less marked.

That sick persons are not intoxicated even by enormous doses of alcohol gives us no evidence whatever that it is doing good, nor on the other hand is it a reason for believing that it does harm. It is an interesting but a wholly neutral fact so far as the therapeutic value of alcohol is concerned, and is important chiefly as a warning to those who tend to argue directly from the known effects of the drug in health to its supposed effects in disease.

### THE PSYCHIC EFFECTS OF GIVING ALCOHOL.

(1) On the mind of the physician and of the patient's family or friends.

(2) On the mind of the patient himself.

(1) The virtues of alcohol as a stimulant have been so firmly established in the minds of the laity, that both the patient and his friends are apt to be comforted by the knowledge that it is being given. It does not sound exactly like a drug, its taste is generally not disliked, and the cheering impression that something is being done, and done pretty frequently, is diffused among those who are caring for the patient, and may reach the mind of the patient himself.

By a sort of auto-suggestion, a similar impression is sometimes produced upon the physician as well. It is very hard to sit still and do nothing for the patient, and when we have no very reasonable belief in the efficacy of a drug, it is a relief to the physician's mind to give *something*, especially something that is welcomed by the patient and his friends, and something of which the community generally has a high opinion. Then the soothing effect upon the patient, which the narcotic action of alcohol produces, is indirectly soothing to the physician as well, and increases his willingness to prescribe and to continue the so-called "stimulant." In short, alcohol makes physician, patient and friends more comfortable.

(2) The narcotic action of alcohol, its tranquilizing and benumbing effects upon the nervous system, have been very properly insisted on as a therapeutic influence of considerable importance by Cushny and by Meltzer in recent addresses on the use of alcohol in disease. To save the patient from worrying about himself, from broodings on the cause and apprehensions about the future of his disease is certainly to do him a service. But

we cannot, at the same time, praise alcohol for bringing the patient into so passive and vegetative a condition and expect also to take advantage of that active, fighting, determination to get well, which many physicians suppose to have a real effect in combating disease. Either the tranquillity or the actively resistant will-power of the patient must be sacrificed. Whether either factor has any genuine influence on the course and outcome of disease is entirely a matter of guess work. We have no definite knowledge in the matter, and all that I mean here to point out is, that if we are to maintain that the narcotic effect of alcohol is beneficial, we must give up the idea that the patient's will-power is an important factor in his recovery.

But although it is generally assumed that alcohol has a benumbing effect, and so a tranquilizing effect upon the patient, it has not been my experience that any such effect is always or even usually to be observed. That very striking *neutrality* of alcohol, which has been my chief lesson throughout all the other observations which I have made on its action, has impressed me and surprised me afresh in studying its psychic effect. Only in four out of the 69 cases in which I have watched for the tranquilizing effect of alcohol has any such effect been noticeable. In the vast majority of patients as I talked with them several times each day during a period of about six weeks, no change whatever in the prevailing mood could be determined. The down-hearted patients were not notably more or less down-hearted, the cheerful ones were neither more nor less cheerful. One patient in especial, in whom the dose of 60 ounces of champagne per twenty-four hours, was suddenly cut off, showed not the slightest psychical change that I could detect.

A few of the typhoid patients seemed to sleep a larger part of the day during the time when alcohol was given them, but it was difficult to be sure that this change would not have taken place spontaneously. In one patient who became more sleepy just after the alcohol was given him, the sleepiness continued just the same for the next ten days after the alcohol was withdrawn, in fact until the temperature became normal.

Very likely finer psychical tests, such as Kraepelin employed in his studies on typesetters, would have shown that, in disease as in health, the associations and reactions necessary for the more delicate psycho-motor processes are slowed by the action of the drug; but that any constant effect was produced on the temper, mood and spirits of the patient I could see no reason to believe.

### MEASUREMENTS OF BLOOD PRESSURE.

From this résumé will be seen that no considerable amount of work on the estimation of blood pressure in human beings during the administration of alcohol has so far been done. Rosenfeld's observations are, it seems to me, conclusive, so far as concerns the effect of the drug upon dogs, but we cannot immediately reason from its effect in healthy or in tired dogs to its effect in sick men. Accordingly, I have undertaken a series of measurements of the blood pressure before, during and after the administration of alcohol in patients for the most part sick with typhoid fever in the medical wards of the Massachusetts General Hospital. I am especially indebted for the opportunity to carry out these researches to the kindness of Drs. F. C. Shattuck and R. H. Fitz. My method of work has been the following:

Two instruments have been used: the Riva-Rocci machine for the estimation of the maximum or systolic pressure, and Oliver's hemodynamometer for the estimation of minimum or diastolic pressure. The working of these instruments may be explained in a few words.

The Riva-Rocci apparatus consists of a dilatable rubber armlet about three inches wide, covered with tough canvas as a support to the rubber, and arranged by means of a series of hooks and eyes so that it can be tightly fitted to arms of any size. By means of a V-tube air is blown simultaneously into this armlet and into the bulb of a mercury manometer. For inflation an ordinary cautery bulb was used.

To use the instrument we attach the armlet snugly around the patient's upper arm about two inches above the bend of the elbow, and force air into it until the radial pulse disappears. When the radial pulse is no longer felt, we note the point to which the mercury column has been forced up and record the reading in millimeters. The instrument appears to be very accurate in the sense that different observers after an equal amount of practice read practically the same independently, and that successive readings by the same observer in the same patient do not vary more than 3 or 4 mm. of mercury. It is very easy to use, and requires very little practice. It is not at all painful to the patient, as I have ascertained by many experiments upon my own arm, and no patient has complained of it in any way, although in some cases more than a dozen readings were taken in the course of a day. No bad effects upon the arm of the patient have occurred, although the cases selected were mostly typhoid, in which the thrombosis is well known to be favored. Any errors that there may be in the instrument may be disregarded in a series of comparative observations upon the same patient by the same observer, since the amount of error is presumably the same in all the measurements.

Oliver's hemodynamometer is a more difficult instrument to use. It consists essentially of a hollow rubber pad filled with glycerine and water which is put over the radial artery and through which the pulsations of the artery are transmitted to a rigid rod and thence through a ratchet and pinion adjustment to a needle moving upon a clock-face dial. By exerting pressure with the instrument through the pad upon the radial artery the needle is made to revolve and, by suitable pressure, the pulse may be obliterated. If, then, we relax the pressure upon the artery until a faint pulsation is permitted, this pulsation is represented by slight oscillations of the needle. As

we relax the pressure gradually more and more, the needle upon the face of the dial has a double motion. It moves backward toward the starting point (zero) and it also oscillates back and forth during its course. These oscillations gradually increase up to a maximum as we relax the pressure, after which if we relax it still more, the oscillations begin to diminish and gradually disappear as the needle approaches the zero of the scale. The maximum oscillations in normal persons occur between the points marked 100 and 130 on the scale. But the pressure within the fluid pad of the instrument is the same as that within the artery when its maximum oscillation is reached, and this corresponds, as Howell has shown, to the minimum or diastolic pressure. The fluid pad obviates the difficulties of applying the instrument over the uneven surface of the wrist. The soft and elastic surface of the pad adjusts itself among the structures of the wrist, and gets into contact with the artery at some point, provided the artery is palpable at all. The chief difficulties in using the instrument are (1) to hold it steady without increasing or decreasing the amount of pressure used upon the artery, and (2) to record accurately the position of the swiftly-moving needle. With well sustained pulses it is very easy to see just where the needle starts and where it ends in each of its excursions, but in the bounding pulses of febrile patients this is often very difficult. With a moderate amount of practice, however, different observers do not vary more than five points in the scale in their readings. My instrument reads about twenty-five Hg. too high. Accordingly I subtract twenty-five from each of its readings. This prevents their possessing absolute values, but leaves unchanged the *variations* from hour to hour, which is all that I attempt here to record (see charts).

With these two instruments we have made 1,169 measurements in 58 individuals. We began by taking observations every half hour to determine the amount of range of variation at short intervals. Later we took the measurements every hour and every two hours and finally every four hours as the variations in the smaller periods of time were insignificant, or were excited from moment to moment by occurrences, the mark of which would be as likely to escape detection in half hourly as in four hourly measurements. Thus a cry or groan from another patient in the ward, the approach of dinner or the answering of a question needing some thought would send the blood pressure up a number of points, the rise lasting only a few minutes.

We began our four hourly measurements on febrile patients recumbent in bed and upon unvarying diet. After two or three records with each instrument the patient was given either half an ounce of whisky or an equivalent amount of absolute alcohol properly diluted and flavored. This dose was repeated every four hours for the first twenty-four hours and then doubled and continued for twenty-four hours more. After that it was, in the majority of cases, omitted, although in a few it was continued several days more in order to ascertain whether any further effect was produced after the first forty-eight hours. After stopping the alcohol we continued our readings for at least twenty-four hours and often longer.

Among the cases studied were 25 of typhoid fever, 2 of pneumonia, 2 of chronic valvular heart disease, 2 of malignant endocarditis, 2 of gonorrheal arthritis and 1 each of the following: pleuritic effusion, Addison's disease, cirrhosis of the liver, thrombosis of a leg vein, tuberculosis peritonitis, myelitis and phthisis.

Summing up in a few words the total result of these many measurements: They indicate that in cases of the type studied, alcohol has no considerable effect either upon the heart's action or upon the tension of the peripheral vessels that can be measured by the instrument employed. I must confess that this result was a great surprise to me. Some effect, either for good or evil, some cardiac stimulation or some vascular relaxation I had certainly expected to see, but the result, like all those obtained in my investigations of the effects of alcohol on other functions of the body, was practically *nil*.

The following charts and tables give further details of the work:

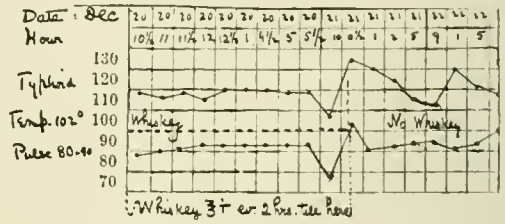

CHART IV.—Shows records of frequent pressure measurements in a case of typhoid with and without whisky.

## SUMMARY AND CONCLUSIONS.

(1) In 41 patients, mostly cases of typhoid fever, 1,105 measurements of the blood pressure were made before, during and after the administration of alcohol in therapeutic doses. Neither the maximum nor the minimum blood pressure showed any variations that could reasonably be referred to the action of the alcohol. So far as was determined by the methods and in the cases used in this research, the action of alcohol upon the circulation was *nil*.

(2) The same neutrality and apparent inertness of therapeutic doses of alcohol in relation to the temperature, pulse rate, respiration rate, appetite, sleep, delirium and secretions (renal and cutaneous) of 309 patients suffering from a great variety of diseases was the total impression derived from 2,160 observations in these cases.

(3) These observations are not interpreted as proving that alcohol is useless or useful in disease.

As a narcotic and vasodilator it may have an important place in therapeutics.

(4) More important probably than any of the questions investigated so far is the problem of the effect of alcohol upon the power of the sick man's blood to protect him against infection and other harmful influences. The studies of Abbott and of Mircoli have begun to clear a path in this direction, and we have a certain amount of evidence relative to a similar problem in the lower animals. But as the results of studies regarding the action of alcohol upon animals or upon healthy men cannot be used as evidence of its action in sick men, there is a good field for experimental work in this direction along the lines of Ehrlich's newer methods.

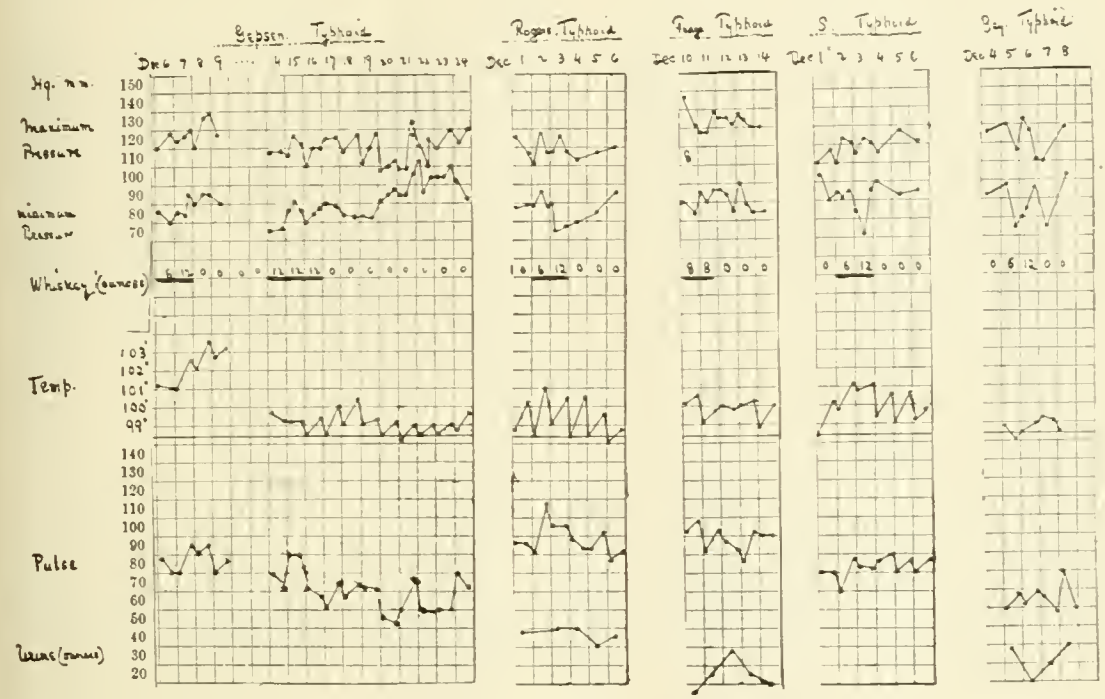

CHART V.—Variations in blood pressure measured every four or eight hours in cases of typhoid, before, during and after whisky.

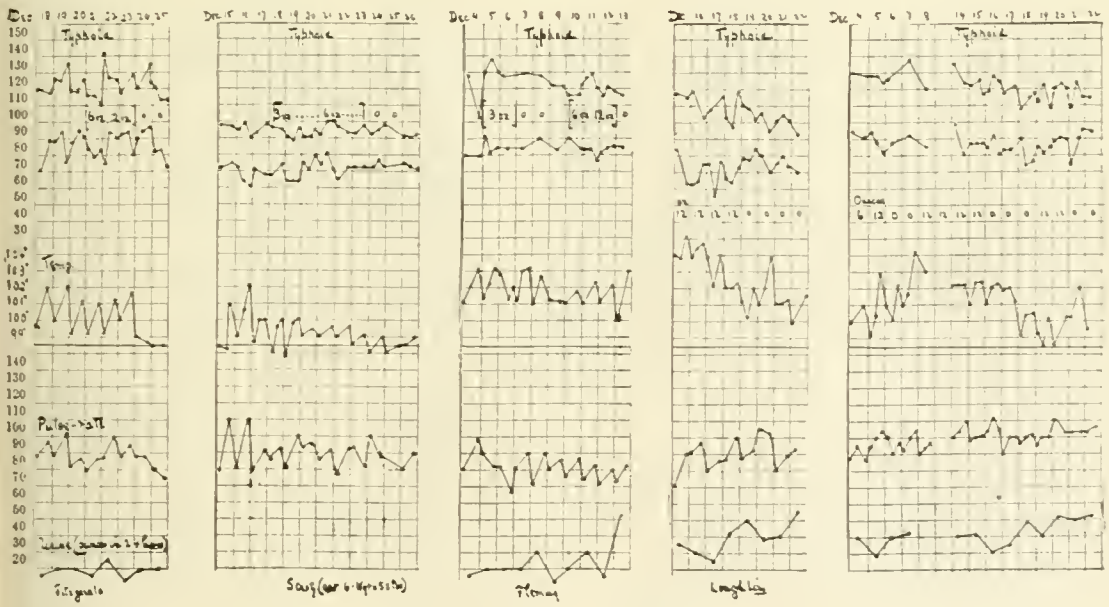

CHART VI.—Same as Chart V.

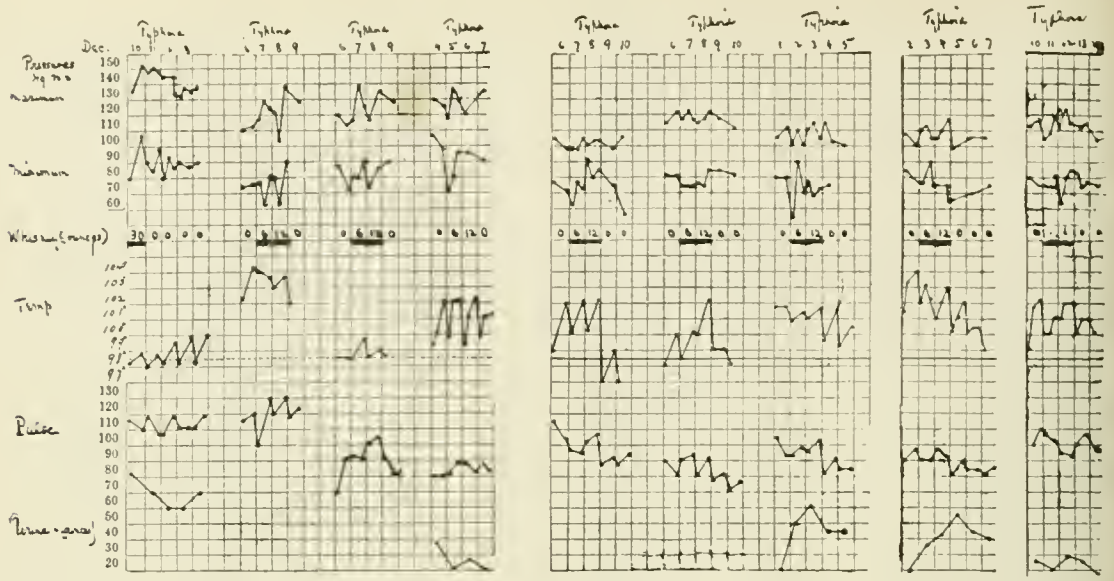

CHART VII.—Same as Charts V and VI.

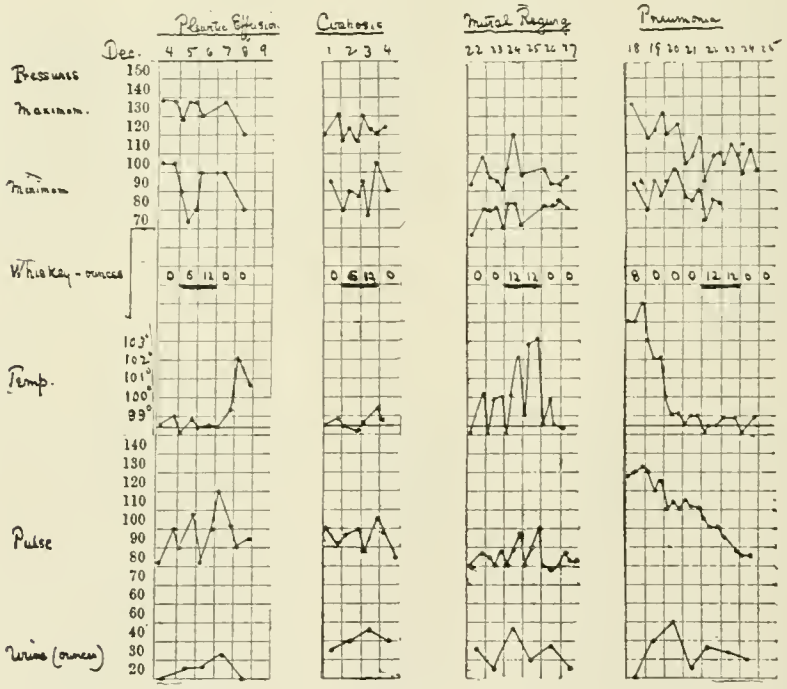

CHART VIII.—Blood pressure in various diseases before, during and after whisky.

## MALIGNANT TUMORS OF THE TESTIS.

BY WILLIAM B. COLEY, M.D.,

OF NEW YORK;

SURGEON TO THE GENERAL MEMORIAL HOSPITAL; ASSOCIATE SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

Malignant disease of the testis is far more likely to be sarcoma than carcinoma. I have personally observed 18 cases of tumors of the testis, of which 17 were sarcoma, and 1 teratoma.

As regards the age of the patients, while malignant disease of the testis is very rare in children, it frequently occurs in young adult life, contrary to the opinion of Butlin, who states that it rarely occurs in adults under thirty years of age. More than one-half of my own cases were young men between twenty and thirty years of age; two of my cases were nineteen years of age, none being younger than that. Nine were between twenty and thirty years of age; five were between thirty and forty years of age; one was between forty and fifty years of age; one was fifty-five years old. These figures do not bear out the statement of some, that sarcoma of the testis is a disease of childhood and old age.

With reference to the etiology, trauma plays a very important part. In 50 per cent. of my own cases there was a distinct history of antecedent injury. In most of these cases the tumor developed so quickly after the injury that there could be no question as to the latter's etiological significance. While at the present day some of the best pathologists refuse to believe that injury has anything to do with the development of malignant disease, the clinical evidence in support of the view that it is of great etiological importance, is very strong.

Antecedent injury in carcinoma of the breast is variously estimated at from 12 to 50 per cent.

Taking sarcomatous tumors as a class, there is a distinct history of antecedent injury in fully one-third of the cases, while in sarcoma of certain localities this percentage is much higher. In sarcoma of the breast every case that I have observed had a local injury prior to the development of the tumor. In sarcoma of the testis there was a local injury to the testis a short time before the tumor was noticed, in nearly one-half of the cases. The very complete statistics of Kober (*Am. Jour. of Med. Sciences*, 1899, Vol. 117, p. 35) giving a carefully tabulated series of 105 cases of sarcoma, collected from literature, shows a history of antecedent injury in 43 per cent. of the cases.

Of 51 malignant tumors of the testis collected by Curling, 6 occurred in patients below the age of twenty years; 5 were under fifteen years. Of 41 cases collected by Butlin, 5 occurred during the first fifteen years of life, the youngest in a child aged eight months.

He believes that there are two periods of life in which the disease occurs more frequently, first, from birth to the age of ten years; second, in the decade from thirty to forty. The great majority of the cases of sarcoma of the testis are of the round-celled variety. The few cases of spindle-celled sarcoma that were collected by Butlin all occurred in patients under ten years of age. While glandular infection as a rule is either absent or only occurs in the latest stages in sarcoma in general, this is not so in sarcoma of the testis. Here we find that involvement of the inguinal and retroperitoneal glands takes place very early.

*Diagnosis.*—The diagnosis of malignant disease of the testis is, as a rule, not difficult. The condition that most closely simulates it is tuberculosis of the testis, but only very rarely does this cause much difficulty. I have recently operated upon a case of tuberculosis of the testis, which very closely resembled sarcoma both as regards clinical history and physical characteristics. The disease was of short duration; there was a history of antecedent injury, smooth symmetrical enlargement, no involvement of the skin, no thickening of the cord; a small amount of fluid in the tunica vaginalis; no family history of tuberculosis, no evidence of tuberculous disease elsewhere. The diagnosis of tuberculosis rather than sarcoma in this case was made almost entirely upon the varying consistence of the tumor itself. In sarcoma the tumor, as a rule, is of uniform consistence, while in tuberculosis the consistence varies greatly, the epididymis being harder than the testis proper. Of course, in the later stages of tuberculosis the enlargement of the cord, early adhesion and ulceration of the skin render the diagnosis perfectly easy. The fact that in tuberculosis the epididymis is nearly always primarily involved, is also an important aid in establishing the diagnosis.

In teratoma, of course, the tumor, being made up of different kinds of tissue, necessarily varies much in consistence, but the larger size and involvement of the entire testis, makes it easy to differentiate it from tuberculosis of the testis.

*Prognosis.*—A careful study of all the recorded cases of sarcoma of the testis, does not permit me to agree with the statement of Kober that "The results of operative interference are very gratifying."

While in my own experience I have never seen a patient cured, it is but fair to state that the complete statistics of Kober show 9 patients that lived and were free from recurrence from 3 to 15 years. His own tables give 11 cases, but a more careful study of the tables shows that in 2 cases there was an error and instead of 9 years, they had remained well less than one year. The 9 cases cured out of 105, gives a percentage of

8.5, lower than perhaps any other variety of sarcoma, except periosteal sarcoma of the femur, which shows less than two per cent. of cures from hip-joint or high amputation.

The duration of the disease is rather shorter than in sarcoma of other localities. Kober's statistics show that in 99 cases the duration was from a few weeks to six months in 28 cases, and in 47 cases it was less than a year, and in 71 cases less than two years. In a few cases the tumor had existed a long period before operation, in 10 cases varying from six to twenty-six years. The rapid course of the disease after castration is illustrated by Kober's tables. Of 114 cases operated upon, 37 were not traced. Of the remaining 77, 41 died in from a few days to three years. Of these 41 fatal cases, 23, or 56 per cent. died within five months, of metastases: 11 others died from seven to twelve months after operation, making 83 per cent. of the fatal cases that died within the first twelve months after operation. Two patients lived beyond three years, but died later of recurrence.

While personally I have not seen a single case of sarcoma of the testis cured, it is but fair to state that in only a small proportion—about one-fourth—did I see the cases at an early stage, the remainder having been treated for recurrences at varying periods after castration. Hence, my own statistics are of little value in forming an estimate of the prognosis of primary sarcoma of the testis.

*Treatment.*—I believe that operation consisting of complete removal of the testis and cord as high up as the internal ring, as soon as the diagnosis is made, is the only proper and rational treatment.

In addition to this I would strongly advise a course of treatment with the mixed toxins of erysipelas and *Bacillus prodigiosus*, for two or three months after operation as a prophylactic measure. I have thus far had the opportunity of using the toxins only in advanced recurrent round-celled sarcoma of the testis, with large retroperitoneal tumors. In some of these cases there has been marked improvement and retardation of the growth for a considerable period, but no permanent cure has resulted. In one case the patient had a long course of X-ray treatment, lasting for months, without any appreciable effect in checking the disease.

The only hope of better results lies in earlier diagnosis, and the practice of delaying for weeks while trying the effect of mercurial ointment, so universally advocated by text-books and surgeons, is, I believe, to be strongly condemned. In the great majority of cases the diagnosis can be made in the early stages if a careful examination is made. In cases of doubt, the dangers of delay are so great that immediate exploratory operation is demanded, with castration, if section of the tumor confirms the suspicions of sarcoma. One should never remove a section and wait for a microscopical diagnosis, since the danger of infected cells being carried to remote parts by the blood current, is, I believe, a real one.

The prognosis of teratoma is very good, yet, though pathologists are inclined to classify this variety as a benign growth, not infrequently recurrence and metastases do occur. My own case is still well over two years after operation.

The following are reports of cases:

*Round-Celled Sarcoma of the Testis Recurrent in the Abdomen. Case I.*—R. C., thirty-three years of age; F. H. good; no history of trauma. The patient first noticed pain in the left testis in January, 1893; the left testis also appeared slightly larger than the right and increased rather rapidly in size. Two months later castration was performed by Dr. A. T. Cabot of Boston, after which the patient remained well for over two years. In July, 1895, he began to have pain in the loins and at about the same time he noticed a swelling in the abdomen.

The patient first came under my observation Nov. 25, 1895, at which time there was a large mass extending from the free border of the ribs down to two inches below the umbilicus filling up nearly the whole left side of the abdomen. The mass was hard, deeply fixed, probably originating in the retro-peritoneal glands. The erysipelas toxins were tried for two weeks without any apparent effect.

*Recurrent Round-Celled Sarcoma of the Testis and Abdomen. Case II.*—C. B., aged nineteen years, first noticed a swelling of the left testicle in January, 1895. The history contains no reference to trauma. The tumor slowly increased in size, without pain, until one year later it had reached the size of two fists. It then became slightly painful and the patient began to complain of numbness of the leg. Examination at this time by Dr. McBurney showed the entire pelvis and abdominal cavity extending as far as the umbilicus, filled with a hard, firmly fixed mass, partly solid and partly semifluctuating. The testicle was removed by Dr. McBurney. An incision was made into the iliac region allowing the escape of five to six ounces of serosanguinolent fluid. The tumor proved to be a typical round-celled sarcoma. The patient's general condition was so bad that no further treatment was advised.

*Round-Celled Sarcoma of the Testis of Traumatic Origin. Case III.*—E. F. K., aged twenty-two years, F. H., good. While attempting to learn to ride a bicycle in the spring of 1896, he fell and injured the left testis. A few weeks afterward he noticed an increase in the size of the injured testicle, but there was no pain until the growth had reached considerable size. In August, 1896, it had become about as large as a closed fist, was slightly painful but not tender. Castration was performed by a Philadelphia surgeon. There were no enlarged glands in the groin. In May, 1897, about eight months after the operation a return of the disease was noticed in the wall of the scrotum and at the lower end of the cord. A second operation was performed

June 24, 1897, the glands in the groin and the redundant portion of the scrotum being removed. Within two weeks after the operation the patient developed severe neuralgic pain in the lumbar region and down the left leg; the pain increased in severity and during the month's hospital treatment he lost 40 pounds in weight. At this time he began to have increasing gastro-intestinal disturbances, severe abdominal pain, nausea and vomiting. Physical examination at that time showed in the iliac fossa a hard, firmly fixed mass, extending nearly to the diaphragm and in the central portion projecting forward to the anterior abdominal wall. The patient died one month later. A very complete autopsy was obtained in this case, the examination showing that nearly every organ in the abdomen and thorax was involved with typical round-celled sarcoma. The entire duration of the disease in this case was one and a half years, or one year after the first operation.

*Recurrent Round-Celled Sarcoma of the Testis. Case IV.*—C. M., twenty-eight years of age, F. H., good. The patient first consulted me on April 26, 1899, having been referred to me by Mr. Watson Cheyne, of London. He gave a history of having fallen from a bicycle three years before, bruising his knee and right groin, causing a swelling of the glands sufficient to keep him in bed for a few days. About two years ago, or one year after the injury, he first noticed a swelling of the right testis. This increased slowly in size without being painful. December, 1898, it measured 12 inches in circumference, was smooth, symmetrical and was at first supposed to be hydrocele and tapped without result. Dec. 10, 1898, castration was performed by Dr. Alfred Fripp, of London. The patient made a good recovery and was well until four months later, when he noticed discomfort in the abdomen, probably originating in the mesenteric glands. The patient came under my care in the latter part of April, 1899, and was treated with the mixed toxins of erysipelas and *Bacillus prodigiosus* from May 1 to October 1. At first there was a decided decrease in the size of the abdominal tumor and improvement in symptoms and general health. The patient was able to go about and a great part of the time during the summer played golf. In October he noticed some loss of weight and the tumor began to increase perceptibly. His condition grew worse rather rapidly from this time on, and three months later he developed a recurrent growth in the spine, causing great pain and, finally, paralysis. He died in the spring of 1900. The entire duration of the disease in this case was three years, or about one and a half years after castration.

*Round-Celled Sarcoma of the Testis, Traumatic. Case V.*—F. H., aged twenty-seven years, farmer by occupation, consulted me July 1, 1898. There was no history of malignant or tuberculous disease in the family. The patient had been well until two years ago, when he was kicked by a horse in the right testicle. A small lump appeared immediately after the injury and, although it never disappeared entirely, it did not increase in size, until about four months before my first observation, when the patient fell through a hay rack, again injuring himself in the same region. Immediately thereafter the old swelling of the testis began to increase rapidly in size. Physical examination made August 8, 1898, showed the right testicle the size of a cocoanut; a portion of the tumor was solid, the remaining part showed distinct fluctuation, simulating fluid in the tunica vaginalis in addition to a solid tumor of the testis. His general health was perfect, the cord was not enlarged and the patient never had any pain. The diagnosis of sarcoma was made and, in view of the history and physical characteristics, castration was advised. I made the incision over the inguinal canal, as in Bassini's operation for inguinal hernia and the entire testis tunica vaginalis and four inches of the cord were removed en masse. The tunica vaginalis contained from four to five ounces of straw-colored fluid. The solid tumor of the testis weighed 12 ounces and 17 grains. The wound healed by primary union. Microscopical examination showed the growth to be a typical round-celled sarcoma. The patient left the hospital in ten days. A recurrence, however, took place in the abdomen and the patient died within one year of the operation. The duration of the disease in this case dating from the time when the small lump in the testis began to enlarge was scarcely more than a year.

*Round-Celled Sarcoma of the Testis—Trauma. Case VI.*—M.M., single, twenty-eight years of age, driver by occupation, first consulted me Feb. 10, 1900, with the following history: No malignant or tuberculous disease in the family; nine years ago had an attack of gonorrhea. Four weeks before calling on me the patient fell astride a bar, injuring his right testis. A swelling appeared at once and did not disappear. Two weeks later the patient noticed that the swelling was increasing in size. There was no pain at first, but later a slight dragging pain on account of the weight of the swelling set in. Two weeks before I saw the patient he visited the out-patient department of Bellevue and was tapped for supposed hydrocele. Nothing but blood, however, was found. A second tapping was done with the same result. Physical examination at the time I saw the patient, at the Hospital for Ruptured and Crippled, showed a tumor of the right scrotum, the size of an orange, symmetrical in shape and semifluctuating; the skin was freely movable. There was little or no tenderness on pressure. In view of the very rapid development of the tumor, following a rather severe injury, the diagnosis of hematocele with possibility of sarcoma, was made and immediate operation advised. Two days later I operated at the General Memorial Hospital. On opening the tunica vaginalis, about four ounces of dark, grumous blood escaped. The testis was found enlarged to

about three times its normal size and was so soft that it closely simulated fluctuation. Being convinced that it was malignant, I continued the incision up into the inguinal canal and removed the entire testis and cord very high up. The specimen was carefully examined by the pathologist of the hospital and pronounced at first non-malignant. I was so sure, however, from the clinical history and the gross appearance that we had to deal with a sarcoma of the testis, that I insisted on a more careful examination and after numerous sections, the pathologist found an area showing the typical structure of a round-celled sarcoma. At this time there was no evidence of any trouble in the abdomen. The subsequent course of this case is of very great interest.

Within two weeks after leaving the hospital, he was admitted to the service of Dr. B. F. Curtis of the Bellevue Hospital with a large abdominal tumor. March 16th, or less than five weeks from the date of my own primary operation, Dr. Curtis made an exploratory incision and found a large tumor involving the right kidney and probably retroperitoneal glands, the size of a man's head, of soft consistence and surrounded by a thin capsule, closely adherent to the large intestine and stomach, having apparently developed between the layers of the mesentery. Dr. Curtis states that there was almost no glandular involvement and the portion of the tumor, removed for microscopical examination, was pronounced round-celled sarcoma. The patient died on the 18th of April of progressive cachexia and persistent vomiting from pressure on the duodenum.

This case is most remarkable in that the whole course of the disease, from the date of injury, January 10, to the date of death, April 18, was scarcely more than three months. It also furnishes a most convincing example of acute traumatic malignancy, the causal relation between the injury and the development of the sarcoma being beyond question.

*Recurrent Sarcoma of the Testis. Case VII.*—W. T., aged thirty-two years; born in the U. S., no trauma, was seen in consultation with Dr. Dowd, January, 1900. The patient first noticed a small lump at the bottom of the right testis in June, 1899. This grew rapidly, but was never painful. Nov. 15, 1899, the testis was removed by Dr. L. Boulton Bangs. The tumor measured nine inches in circumference. The patient complained of severe pain in the back before operation, exactly the same as at the time of his admission to the General Memorial Hospital, although no enlargement of abdomen was noticed at that time. A curious phenomenon as regards the periodicity of the pain was observed in this case. Very severe pain developed in the groin and back every Tuesday and Friday at 3 P.M. Shortly after the operation a tumor was discovered in the abdomen and January, 1900, several masses could be felt in the abdominal cavity, apparently the retroperitoneal glands. There was also local recurrence in the cord and the patient died a few months later. The whole course of the disease in this case was a little more than a year, and less than six months after operation.

*Recurrent Round-Celled Sarcoma of the Testis, no Trauma. Case VIII.*—L. K., twenty-eight years old, born in Russia; occupation, shop work. The patient consulted me March 29, 1901, having been referred to me by Dr. W. B. De Garmo. Two years prior to this, he first noticed a painless enlargement of the right testis. The first operation was done on Dec. 8, 1899, by Dr. De Garmo at the Post-Graduate Hospital. A recurrence was noticed in the glands of the groin in September, 1900, about ten months after the operation. In December, two months later, he began to have severe lumbar pain and there was rapid decrease in weight. On March 29, 1901, when he consulted me, there was a large recurrent mass in the abdominal cavity in the retroperitoneal region. The patient was greatly emaciated and his condition was considered hopeless. Of the exact duration of his life, after this, I am not aware.

*Round-Celled Sarcoma of the Testis, Recurrent. Case IX.*—P. H., thirty-eight years of age; mining engineer by occupation. F. H., maternal grandmother died of cancer of the breast. P. H., the patient, has always been a great horseback rider. Four years ago he first noticed a small painless enlargement of the left testicle. As the tumor enlarged in size, he had some discomfort and dragging sensations in the cord. Operation one year after discovery of the trouble. The patient remained free from a return for two years and at this time he passed a satisfactory examination by the Equitable Life Insurance Co. Shortly after that he began to have pain in the back and was treated for lumbago. Instead of losing flesh his weight, which normally was 137 pounds, had increased to 145, at the time of my first examination, July 16, 1900. This increase was largely due to the great edema of the leg and thigh. At this time he had a great deal of pain which was worse at night. His left leg began to swell Jan. 1, 1900. Physical examination July 16, 1900, showed the left leg and thigh very greatly swollen and a hard mass in the left iliac region. The patient's general condition was fairly good, although he was slightly emaciated. He was treated for several months with the mixed toxins of erysipelas and *Bacillus prodigiosus*, and although there was marked temporary improvement, after a while the toxins seemed to have lost their effect and the disease progressed, causing death about six months later.

This case is distinct from the fact that the patient remained in perfect health for more than two years after operation and then had a recurrence which proved fatal.

*Round-Celled Sarcoma of the Testis. Case X.*—T. B., thirty-two years old; Italian, consulted me April 1, 1902. He stated that he had had a small tumor of the testis for twenty-two years; there was, however, no increase in size until eight months ago when it began slowly and

steadily to increase in size. There was no pain. At the time of my observation the tumor was of about the size of an orange, symmetrical in outline, skin normal, consistence slightly varying, testis and epididymis both involved; cord not enlarged. Operation April 2, 1902, at the General Memorial Hospital. Testis and cord were removed through Bassini's incision for hernia; there was no fluid in the tunica vaginalis in this case. Subsequent history is not known.

*Sarcoma of the Left Testis. Case XI.*—R.M., aged twenty-seven years, F. H., good. P. H. Fourteen years ago, while playing ball, the patient was struck in the left testis. A small lump was noticed which never entirely disappeared, but did not increase in size until six years ago. Castration was performed Oct. 3, 1900, by Dr. James Peterson. A second operation was performed shortly afterward for local recurrence. The patient was referred to me by Dr. Peterson, and physical examination April 23, 1900, showed a large recurrent mass in the abdominal cavity. No further treatment was advised as the patient was greatly emaciated and the mass in the abdomen was so large that it was not thought advisable to try the toxin treatment. The subsequent history of the case I have been unable to trace.

*Sarcoma of the Testis—Trauma. Case XII.*—C. G., forty-two years of age. F. H. good; brother died of phthisis. P. H. Eight months ago the patient injured the right testis while lifting, but there was no increase in size. Five months ago he again struck the same testis against a work-bench. Swelling developed immediately and slowly increased in size, causing no pain, except a dull dragging sensation. Physical examination, Oct. 25, 1901, shows the right testis as large as an orange. The whole testis seems transformed into a symmetrical tumor of solid consistence. There is a slight amount of effusion in the tunica vaginalis, no enlargement of the cord, no adhesion to the skin nor any of the characteristics of tuberculous disease. Clinical diagnosis: Sarcoma. Patient refused operation, hence there is no microscopical confirmation of the diagnosis.

*Recurrent Sarcoma of Testicle. Case XIII.*—A. W., fifty-five years old; F. H. good; occupation, painter; no history of trauma; does not ride bicycle. He first noticed a painless swelling in the right testis in July, 1900; this slowly increased in size but never became painful. July 24, 1902, the patient was operated upon at the German Hospital, by Dr. Willy Meyer, the left testicle being removed. A recurrent growth soon appeared on the right side, just above the testis. This was removed October 7 and microscopical examination made at the German Hospital showed the growth to be large round-celled sarcoma. Rapid recurrence followed the second operation, recurrence taking place in the pubic and inguinal regions, also at the base of the scrotum. The patient was referred to me by Dr. Willy Meyer, Nov. 24, 1902. Physical examination at that time showed an ulcerating mass in the left groin extending to the base of the scrotum involving the entire pubic region; retroperitoneal glands not markedly involved. General condition of the patient fair; has apparently lost little weight. There is considerable discharge from the growth of extremely foul odor. The patient entered the General Memorial Hospital November 25 and received X-ray and toxin treatment for about two months. The foul odor, which was very pronounced at the time of his admission, nearly disappeared under the treatment and there was a slight decrease in the size of the tumor. The patient was discharged owing to insubordination at the end of this time.

*Recurrent Round-Celled Melanotic Sarcoma of Left Testis, Traumatic. Case XIV.*—G. S., twenty-nine years of age; perfectly well until he fell from a bicycle in August, 1896, injuring the left testicle. A tumor appeared in the early part of September, within two to three weeks of the injury. This increased rapidly in size. The first operation was performed in January, 1897, by Dr. Millbank of Albany. Recurrence quickly followed in the cord and inguinal glands. Four operations were performed, the last two by myself. The erysipelas toxins were then used for two to three weeks, without effect. The tumors quickly recurred and systemic infection soon followed causing death in January, 1898. The entire duration in this case was fifteen months.

*Teratoma of the Testis. Case XV.*—Mr. J., twenty-seven years of age, German, always in perfect health; no trauma. In April, 1900, he first noticed a slight enlargement of the testicle. This increased uniformly, without pain, until the time of my first observation, Dec. 10, 1900. Physical examination then showed a tumor about the size of an orange, symmetrical in shape, very firm in consistence, giving all the characteristics of a sarcoma of the testis, which was the clinical diagnosis made. The glands of the groin were not enlarged and general health was perfect. Operation Dec. 12, 1900, consisting in removal of the testis and the cord as high up as the internal ring. The wound healed without suppuration. Feb. 18, 1903, the patient was exhibited before the Genito-Urinary Section of the Academy of Medicine, in perfect health.

## ALCOHOLISM IN WOMEN.*

BY AGNES SPARKS, M.D.,
OF BROOKLYN, N. Y.;
PRIVATE SANITARIUM FOR INEBRIATES.

IN my paper "Alcoholism in Women, Its Cause, Consequence and Cure," read before the New York Medico-Legal Society, October 20, 1897 (*N. Y. Medical Record*, Nov. 13, 1897), attention was called to some points peculiar to this neurosis in women.

From its heredity she is more often exempt than man. We know families in which the sons

* Read at the Annual Meeting of the American Association for the Cure of Inebriety, Boston.

inherit the father's inebriety almost as naturally as they do his name or fortune, while the daughters show the strongest repugnance for the poison, especially if the mother be the inebriate. From physical ill health and discomfort she seeks relief in the delusive draft, and so tends swiftly and surely to cross the line where volition ends and disease begins, thus proving anew the popular error as to mere vicious indulgence. Secret drinking is the rock upon which many a woman's life is wrecked. With innate modesty she shrinks from publicity, and often so skilfully hides this weakness from family, friends and even her physician that ere they are aware, she is a confirmed inebriate.

Such a case was brought to my care the past year. Mrs. A., age twenty-nine years, of good ancestry and training, began taking beer by medical advice seven years ago as an aid to lactation. From this she indulged in wine and stronger drinks, in increasing amounts, until for nearly a year before coming under treatment, she was drinking one quart of whisky each day. As to be expected, the havoc from such excess was soon in evidence. Collapse came suddenly, with complete paraplegia and entire loss of power over bowel and bladder. Respiration was irregular and heart action weak—120 and over. There was general anesthesia, incoordination of arms and fingers, and the special pains of alcoholism girdling limbs about the joints. Two years ago she began having attacks of petit mal in the early morning before rising, and these continued, at irregular intervals, until the whisky was entirely withheld. Amnesia was a special feature, making her family think her insane, and despair of her recovery. There were visual hallucinations, with delusions of persecutions, great fear of poisoning, and memory was a complete blank. It was the most pronounced and pitiable case of alcoholic excess I ever knew.

As a prelude to special treatment, active measures were taken to eliminate the poison through every possible channel. Under tonic treatment she improved slowly, but surely. Full feeding, much milk and malt were continued for months. Strychnine nitrate, with solution of arsenic and gold—arsenaura—were given. Electricity, massage and suggestion were used. At the end of four months she had so far recovered as to leave sanitarium care, and return home, where, under glycerophosphates, she continues to improve.

Some points in this story merit more than passing notice. The risk in some cases of prescribing even beer, is large. The need of careful search in obscure and recurring illness, to settle the question of secret drinking, is obvious. The relation of alcoholism to epilepsy is of great interest and far-reaching import. Certain facts in recent papers by Dr. Crothers and Dr. Louise Robinovitch prove a close connection between these neuroses. Not only is the toxic power of alcohol acutely genetic, but the chronic curse is so marked that 64 per cent. of epileptics have an alcoholic ancestry. The wisdom of limiting offspring in such patients as Mrs. A. for several years, till the system has regained its own, is also obvious. Lastly, the result proves the value of well-directed, persistent treatment, and should promote optimism in those inclined to think such cases beyond the reach of the healing art.

---

## ALCOHOLIC TOXEMIA: ITS PATHOLOGY AND TREATMENT.

BY THOMAS D. CROTHERS, M.D.,
OF HARTFORD, CONN.;
SUPT. WALNUT LODGE HOSPITAL, ETC.

IT may now be taken as demonstrated that the various affections of the body and mind which are produced directly or indirectly by alcoholism are due to toxemia. A study of the pathology of such diseases shows that alcohol acts in a very similar manner to other poisons. The effects may be the result of one or two glasses of spirits or of a long course of drinking. They differ of course in degree, but are more or less the same in character. This fact having been established, it becomes essential that the profession should revise and indeed revolutionize its method of dealing with such conditions. There are no affections in modern times that call so frequently for medical care as those traceable to alcohol, and none which are treated so inefficiently and dangerously, because of the false conception that has hitherto prevailed as to their origin and cure.

The first mention of delirium tremens, as such, in medical literature was made by Dr. Thomas Sutton, of London, in 1813. Twenty years later the term found its way into the text-books, from which it is now commencing to drop out. It is in reality a rare disease, though other forms of alcoholism, which are often confused with it, are sufficiently common. The characteristic features of delirium tremens are muscular trembling and peculiar delusions. The general name for such diseases as a class is alcoholism.

A word as to the etiology of so-called alcoholism and diseases following it. These diseases are commonly supposed to result from alcohol alone. This is an error; the same symptoms follow diverse and most complex causes. Thus a man who has been thrown from a wagon and stunned, on recovering commences to "see sights and hear sounds," and if he is known to have been a drinking man the delusions are at once put down to alcohol. Yet, the alcoholism may have been only an indirect and predisposing cause, the direct cause being the traumatism. The pathological changes which follow alcoholism are alike, and resemble those which follow from other causes, as for example, traumatisms, infectious diseases, fevers, inflammations and some other acute diseases. In all cases followed by delirium, there are clearly states of narcosis for which toxins are largely responsible.

The progress of different cases varies widely, the disease sometimes extending over years, while at other times it lasts only a short time, but there

are the same general symptoms in all serious cases. Thus if a man suddenly develops delusions —thinking he hears sounds that no one else hears, or sees things which are non-existent, and if afterward he gets into a state of violent excitement accompanied by muscular trembling, the prognosis is more or less grave. If, on the other hand, he wakes up confused, wondering where he is, and who other people are that are in the room, the probability is that the condition is transient and will soon pass away; but it is none the less evident that a pathological change has taken place. The toxemia is present in both cases. When the symptoms take the form of so-called delirium tremens, it shows that organic changes have occurred of a serious character.

In all these cases alcohol acts first on the blood vessels. The vasomotor nerves surrounding the blood vessels become paralyzed. They alternately dilate and contract, breaking up the uniform flow of the blood and diminishing the nutrition of the artery. Then follows mechanical obstruction, with increased labor of the heart, also increased tension and feebleness. This condition is followed very soon by other changes due to the failure of nourishment. The coating of the arteries becomes thickened or thinned at different points and fibrous deposits form, producing sclerosis. This process is more prominent in the arteries of the brain, but corresponding changes may occur all over the body. As a result the heart increases in size and becomes hypertrophied, and cirrhosis of the liver and other serious affections of like character occur. The men seen on the street with extremely red congested faces are suffering more or less from vasomotor paralysis. Later on venous congestion will appear, and the whole circulatory system will become deranged, because oxidization has diminished.

Secondly, alcohol acts on the blood, reducing the number of red corpuscles which carry the oxygen. At the same time the number of white corpuscles is increased. Their lives become shorter and shorter, and ultimately they divide and subdivide, destroying the material that was intended to give nourishment to the blood vessels.

Alcohol, in the third place, acts on the nervous tissue, producing the condition which is commonly known as neuritis. A person long given to alcoholic indulgence complains of pains in the legs, or arms, or other parts of the body. It is called rheumatism, and very frequently he is treated for that. In reality, it is neuritis. It is a very common disease—beer drinkers in particular suffer from it; but it is seldom diagnosed as such. Most frequently, it is supposed to be rheumatism, and the patient is treated accordingly with all sorts of drugs and outward applications. At the same time, he continues drinking, and therefore it is not surprising that he does not improve. All the while that he is taking medicines given by his physician to remove the symptoms, he is feeding the toxins which produce them.

In regard to the action of alcohol on the blood cells some interesting experiments have been made on dogs, which were given certain quantities of alcohol and afterward killed. An examination of the brain cells of these dogs showed that the same changes had taken place that occur in animals subjected to excessive fatigue. Thus there was a shrinking of the coats of the nerves and a consequent corrugation of the nerve cells: and anemia and sclerosis followed. Yet recently, at the Academy of Medicine, a doctor read a paper on the subject of arteriosclerosis, and mentioned spirits as a good remedy for this disease. In other words, for the cure of a condition of anemia and fatigue he ordered a drug which produces the same pathological conditions. The same speaker incidently mentioned that a large proportion of those who died from arteriosclerosis were physicians. In fact he said it was peculiarly a doctor's disease, and the cause he suggested was worry! Perhaps worry may have something to do with it, but it is also possible that doctors like other people indulge too much in the use of stimulants.

Another curious fact which may be touched upon in passing is that statistics show that in modern times the mortality from delirium tremens has been reduced from 50 per cent. to 10 per cent., while the mortality from other forms of alcoholism, which used to be 10 per cent., has increased to 50, 60 or perhaps 70 per cent.

Having given this general statement of the results of alcoholism, we come to the important question of treatment. The usual custom is to take away the alcohol gradually with the view of avoiding shock, and then to give the patient narcotics for the purpose of keeping him asleep. I do not believe there is any basis for these theories. The removal of the alcohol is the first thing to be attended to. It should be stopped entirely and at once. There is no shock caused by the taking away of other poisons. Why should we apprehend it in the case of alcohol? What danger there is arises from the fact that, by stopping the production of alcoholic toxins, you may give more room for the play of other toxic agents. These, however, must be dealt with as they arise: the first thing is to remove the alcohol, which is the main cause of the general toxemia. The toxins generally may be expelled from the system by elimination. With a view to this the bowels should be opened by means of salines, and baths and other means used to stimulate the pores of the skin. These two things are absolutely essential—sharp purgation and sweating. The best results follow from prolonged and continuous elimination by this double process.

As to narcotics, I make a point of not giving any drugs of this class until the toxins have been expelled, and neither do I give food until the acute stage has been passed.

When, however, the patient is convalescent, attacks of insomnia may occur, and to relieve these, special treatment, including some of the milder sedatives, may be necessary. In this connection I have found some of the coal-tar products

useful, and good results have been obtained from chloretone. This is a tertiary butylic alcohol of the anesthetic group, and appears to have very marked value where other drugs are impotent. In the insomnia which follows the withdrawal of opium as well as alcohol it works well, without producing any of the unpleasant after-effects which so commonly result from the use of other narcotics. I have given chloretone freely, and not noticed any cumulative action. Its hypnotic effect becomes apparent within half an hour or more. In the so-called delirium tremens, after the bowels have been freely moved and free perspiration established, and the delirium has subsided, it may be given in large doses of fifteen or twenty grains. I may add that it is best given at night. The anesthetic action of the drug is favored by external circumstances. Other narcotics may be given during the day, but chloretone is more effective and pleasing as a night dose. For the neuritis and lumbago so common in alcoholic cases, it is especially indicated, giving in many cases almost absolute relief. Its anesthetic effects seem very general. I have not noticed any resultant trouble in the stomach or derangement of the processes of nutrition. Professor Wilcox, who has written an exhaustive article on the subject, suggests that, as a result of the action of the drug the dendritic filaments lose touch of one another, and the protoplasmic processes are thrown out of contact with the motor cells—sleep, in other words, being produced by cell retraction. My personal experience is that after the drug has been administered, the patient's excitement and irritation quickly subside—not always to the point of sleep or unconsciousness, but at all events to a condition of serenity and quiet dreamy relaxation. So far I have not heard of any bad effects following its use, and therefore I would be disposed to place it among the safest as well as most reliable of the anesthetics and hypnotics now on the market.

The after-treatment should continue—the salines and baths, the latter daily, and with this the bitter tonics of which cinchona is the best. Arsenic is a valuable remedy, and the same may be said of some forms of phosphoric acid. For the alcoholic craze strong infusions of quassia will be found effective. All other remedies should be subordinate to means and measures which act on the skin and encourage elimination. Often this general treatment should be continued for a long time.

---

## INFANT FEEDING—A SCIENCE AND ART.

BY JOHN F. CONNORS, A.M., M.D.,
OF NEW YORK.

*Science of Feeding.*—No subject can be more interesting to the student or general practitioner than the scientific artificial feeding of infants, but the perplexing question is to know what is a scientific method of infant feeding. So many methods have been advocated and the authorities can be quoted with such positiveness both for and against some of the methods, that all attempts at harmonizing different views fail. If this state of affairs means anything, it means that infant feeding is not governed by hard and fast rules.

Peptonized, sterilized, Pasteurized, humanized and modified cow's milk have all been the fashion and each has developed drawbacks. At a superficial glance exact percentage modification of milk looks very plausible, and yet there are few authorities to-day who believe that exact percentages of the different ingredients of cow's milk in the infant's food is the solution of the infant feeding problem. Indeed, Wentworth has shown that feeding mixtures put up in a laboratory, which is supposed to stand for exactness, vary greatly in composition from the prescriptions. If exactness of composition has any value and it cannot be obtained in laboratory feeding it might as well be dismissed as unattainable.

The latest scheme is the so-called differential modification of the proteids of cow's milk so as to resemble those of human milk, it being assumed that the proteids of the two milks are caseinogen and lactalbumin, which vary in relative and actual quantities in the two milks. This looks beautifully simple on paper but ends there. An hour's laboratory work in comparing cow's milk and human milk would do more to clear up this subject in the student's mind than reading a dozen theoretical papers.

Dilute a specimen of cow's milk with three parts of water; add acetic acid until a precipitate ceases to form; allow to settle and filter. Fat and casein will be on the filter paper. Boil the filtrate, and albumin will coagulate. Again filter, and to the filtrate add common salt nearly to saturation, and then a strong solution of tannic acid and albumoses and peptones will precipitate. Dilute another specimen of the milk with one part of water in a cup or bowl, add a drop or two of liquid rennet and slightly acidify with acetic or dilute hydrochloric acid. Now warm up to blood heat and notice the *clotting and shrinking* of the curd during five or ten minutes. Remove the curd and toss it about and notice how leathery it becomes. Repeat the experiments with breast milk and the vast chemical and physical differences between cow's milk and human milk will be appreciated. Furthermore, it has been found that after injecting milk subcutaneously or intraperitoneally into an animal, a serum can be obtained that will precipitate the proteids of that milk and of no other. According to Vaughn and Novy "the serum of animals that have been treated as described with milk, is designated as lacto serum, and it has been found that the lacto sera are in all cases specific in their reaction. Indeed, the discovery of this reaction has shown that the proteids of the milk of different species of animals differ from those of every other species, and it certainly should convince us that it is impossible by any chemical process to make cow's milk a perfect substitute

for the mother's milk in the feeding of infants." Rennet and the acid which cause the proteid of milk to curd are found in the gastric juice, so it will be seen that after milk enters the stomach it naturally ceases to be a "fluid diet." It has been known for a long time that the milks of different species of animals had different curding properties. Chapin has recently called attention to the fact that the curding of milk is to develop the motor functions of the digestive tract, the milk of each species of animals curding in the stomach so as to develop the motor functions peculiar to that species.

The profound effect on nutrition that the failure to develop this function may have, has been shown by some experiments on calves, mentioned by Henry. They ate enormous quantities of milk and grain, but failed to thrive. One calf was given some straw with its food and in a few hours was chewing its cud and thrived thereafter; another calf was not given any coarse bulky food and died. Holt says that some infants who do not thrive on low proteids (highly diluted milk) thrive if less food is given in a more concentrated form (high proteids) which would produce a bulkier curd and thus call forth more mechanical effort. For this reason it is easy to see why peptonized milk in which no curd forms is not suitable as a steady diet for an infant. The formation of a soft curd in the stomach is natural and essential to the normal development of the infant's digestive tract. The essential difference between cow's milk and human milk is in the quantity and character of the curd formed from the proteid by the action of the gastric juice and this difference can not be adjusted by simply varying the percentage or quantity of proteid in the infant's food. Digestion in the cow is a very slow process and in the human being much more rapid. Proteid of cow's milk is much more slowly digested than the proteid of human milk. Nature has a purpose in this, viz., to prepare the undeveloped digestive tract for its future work.

As it is impossible to make human milk, it is essential that there should be some basis for feeding about which there can be no dispute. In this connection it is fortunate that investigators in the nutrition of the lower animals have arrived at some of the same conclusions that have been arrived at in infant nutrition.

Jordan, in his book "The Feeding of Animals," says: "It is time to break away, if we have not already done so, from an undiscriminating adherence to mathematical doses of nutrients, the accuracy of which is supposed by some to outweigh all other considerations and to determine success in feeding. . . . No working animal can be successfully fed by mechanical rules. . . . The ration must be adapted to the species. . . . A ration may be chemically right but practically wrong. . . . The nitrogenous tissues are those that largely determine the vigor and quality of any animal, and as these are formed rapidly in the early stages of growth, a normal and unrestricted growth demands an abundant supply of proteid food. . . . The study of the requirements of the individual animal and the adapting of food to its needs is to be preferred to placing the herd as a whole upon any inflexible ration. . . . Clearly the physiological standards may supplement, and in some measure guide judgment, but cannot take its place. . . . Palatableness is an important factor in successful feeding. Without doubt the success of one feeder as compared with the failure of another may sometimes be due, in part, to a superior manner of presenting a ration, . . . and to manipulations that add to the agreeableness of its flavors."

Holt says: "Success in infant feeding is largely a question of close observation and careful attention to details. . . . Not much is to be expected from fractional variations in the milk percentages when those given are producing a great deal of disturbance. . . . One whose digestion has become seriously deranged while taking milk is sometimes helped by nothing so much as temporarily withdrawing all milk. Such a course is often better than wasting time in juggling with fractional milk percentages, when one or two intelligent trials have been entirely unsuccessful. . . . The most brilliant results are often obtained from as complete a change in diet as possible. . . . Nothing but personal experience will enable one to judge aright as to the combination best suited to the existing conditions. In any case the first prescription must be an experiment. . . . Except to start with too high proteids no more common mistake is made than to continue long with too low proteids. Anemia, malnutrition, and, I believe, not infrequently scurvy, are seen as a consequence of this practice."

Holt's observation as to the effect of low proteids has been experimentally confirmed on pigs many times. The pigs fed low proteids were fat, anemic, stunted, rachitic and in every way poorly developed and of low vitality, being very susceptible to the ravages of hog cholera, while those fed on high proteids were strong, muscular and of great vigor.

It will, therefore, be concluded that the chief requisites of a successful infant feeder are a knowledge of the principles of nutrition especially as they apply to infancy, and an abundance of common sense. He must work out the details of each case and not feel that he has mastered the subject when he has learned some formulas for modifying milk.

Theoretically an infant's food should furnish about the same quantities of fat, proteids, carbohydrates and mineral matter as breast milk, and should also have the property of developing the motor functions of the digestive tract. Cow's milk is by common consent the best basic material to work with. Unfortunately it is very often both chemically and practically wrong. To make it practically right (digestible) by reducing the proteids it may be made chemically wrong

and when made chemically right it may be practically wrong. If all infants could digest cow's milk there would be few cases of malnutrition. The aim in infant feeding should be to get the infant to take plain cow's milk as soon as possible. How soon this can be accomplished depends on the individual infant. In most cases it will not be before the end of the first year and may be longer. By beginning with diluted milk and reducing the dilution gradually, the proportion of milk the infant receives is increased as fast as it can digest it.

In diluting the milk the proteids are reduced to a low point, and every effort should be made to allow as much as possible of the proteid to be converted into tissue. This can be done by making up the fat and sugar that have been reduced in quantity by diluting the milk. When this is done the infant gets practically cow's milk with the indigestible element, proteid, reduced in quantity. It is to accomplish this purpose that the various milk, cream and sugar mixtures have been proposed, and the many mathematical tables devised for calculating the proper quantities to combine. The simplest method that could be employed would be to dilute milk which was extraordinarily rich in fat or cream and add sugar. By the use of bottled milk and the Chapin dipper this method can be employed wherever there is average intelligence.

If the fat in the infant's food is to be kept up to anything like the amount in breast milk, the cow's milk that is to be diluted much must be rich in fat; that to be diluted less, poorer in fat.

One thing that the practitioner should dismiss from his mind is the idea that he can get milk or cream of definite richness unless he makes an assay of each specimen he uses, which is neither feasible nor necessary. Milks of different dairymen differ in richness, and a little experience with the Babcock Milk Tester in testing the milk from a number of dairies would show of how little value in practice are tables showing the *average* richness of milk and cream in fat.

The problem is to fit the milk at hand to the infant under consideration and a direct trial is the only way to find what strength of food can be taken.

In cities a high grade of milk can be obtained in bottles. In the country the dairyman should be instructed to bottle his milk as soon as possible after milking, and set the bottles on ice or in cold water to rapidly cool the milk. This will greatly retard the growth of the bacteria in the milk and will also promote a rapid separation of the cream.

After the cream has risen the top 9 ounces in the bottle when removed and mixed, will be *three* times as rich in fat as the original milk was; the top 14 to 16 ounces *two* times as rich, and the top 20 ounces *one and one half* times as rich. The proteids and sugar in these top milks are about the same as in whole milk. By mixing the cream and milk in the bottle whole milk will be obtained; by removing the cream, skimmed milk nearly fat-free will remain. By using bottled milk the milk is kept freer from contamination, bacterial growth is retarded and milk of almost any desired *proportional* richness in fat can be had without any mental effort. The actual richness of the top milks will vary directly with the richness of the original milk. Whole milk contains anywhere between 3 per cent. and 5 per cent. fat, so the top 9, 15 and 20 ounces will contain respectively 3, 2 and 1½ times these percentages. The top 9 ounces 9 to 15 per cent. fat, top 14 to 16 ounces 6 to 10 per cent., top 20 ounces 4½ to 7½ per cent. For the infant all changes are made by varying the dilution of the top milks and adding sugar, so in practice the richness of the milk makes little difference. In every case the milk is diluted to suit the infant's digestive capacity.

The proportional richness of these quantities from the bottle has been shown to be correct by Chapin, Holt, Judson, Gittings and Wentworth. The only error that can be made is getting less fat in the food some days, which would happen if the cream had not risen completely. This error would always be on the safe side.

To bring the sugar up to the necessary amount, 5 per cent., or one part of sugar to 20 parts of food is added for all dilutions greater than one part of milk to two parts of diluent. One part to 30 or 40 parts for less diluted food.

For removing these top milks a flat bottomed dipper is to be preferred, as it will stand up alone, when the first ounce is taken out of the bottle with a teaspoon, which usually requires the use of both hands. It is surprising how little the cream is disturbed by inserting the dipper. The skimmed milk often shows not over .4 per cent. fat.

The following table will show how to begin with a small quantity of a weak food and gradually increase the quantity and strength without any calculations by simply diluting the milk, also the range of composition of the mixtures when poor or rich milk is used.

| Number and size of feedings | COMPOSITION. Fat % | | Proteids % | | Sugar % | INGREDIENTS. Milk | | Diluent | Sugar |
|---|---|---|---|---|---|---|---|---|---|
| | Poor milk | Rich milk | Poor milk | Rich milk | | | | | |
| 12—2 ozs. | 1.50—2.50 | | .50— .66 | | 6.00 | Dip off top 9 ozs. and use | 4 ozs. | 20 ozs. | 1 oz. |
| 10—3 ozs. | 1.80—3.00 | | .60— .80 | | 6.00 | of this | 6 ozs. | 24 ozs. | 1½ ozs. |
| 9—4 ozs. | 2.25—3.75 | | .75—1.00 | | 6.00 | Top | 9 ozs. | 27 ozs. | 2 ozs. |
| 8—5 ozs. | 2.20—3.60 | | 1.00—1.33 | | 6.00 | Top | 13 ozs. | 27 ozs. | 2 ozs. |
| 7—5½ ozs. | 2.20—3.60 | | 1.20—1.60 | | 6.00 | Top | 16 ozs. | 24 ozs. | 1½ ozs. |
| 6—7 ozs. | 2.25—3.75 | | 1.50—2.00 | | 6.00 | Top | 20 ozs. | 20 ozs. | 1½ ozs. |
| 6—8 ozs. | 2.00—3.30 | | 2.00—2.70 | | 6.00 | Whole milk | 32 ozs. | 16 ozs. | 1½ ozs. |
| Whole milk ad. lib. | 3.00—5.00 | | 3.00—4.00 | | 5.00 | Whole milk | | | |

In measuring the sugar two level tablespoonfuls of granulated or three of milk sugar equal one ounce.

If whole milk is used in making up all mixtures the range of composition for any dilution can be found by dividing the composition of whole milk —fat 3 to 5 per cent.; proteids 3 to 4 per cent.; sugar by 4 to 5 per cent., the number of times the milk is diluted. In diluted whole milk the proteids would be about the same as if the top milks were used, but of course the fat would be less. It will be noticed that the proteids in the feeding mixtures are increased from .1 to .3 per cent. at a time during the reducing of the dilution from 1 to 5 to 1—1 which is all that could be desired in small fractions. The fat in these mixtures is kept rather low, as experience shows that running the fat up too high greatly interferes with digestion.

It will be seen that in the high dilutions of milk the amount of proteid in the food is much less than the quantity found in breast milk (1.5 per cent. to 1.75 per cent.). As the infant's vigor and vitality depends on the quantity of proteid stored up, any method to increase the quantity of proteid the infant can digest should be employed.

It is now accepted that cow's milk is rendered much more digestible by dilution with cereal gruels, partly on account of their mechanical action on the curds and partly on account of their stimulating the digestive process. Oatmeal, barley, wheat or rice may be used in preparing the gruels. Sometimes one agrees better than another. If the plain gruels are used, they must be made quite thin, but if the gruels are dextrinized they should be made quite thick and then dextrinized by the addition of cereo. By this process the starch is rendered soluble, and the amount of proteid in the gruel is about double that in plain gruel. These dextrinized gruels have the same mechanical effect on the curds as the thin plain gruels and add considerable digestible proteid to the diluted milk. The clinical effect of the use of dextrinized gruel as a diluent is best seen in marasmus and subacute gastro-enteric catarrh. Oftentimes infants will take food prepared with this diluent with eagerness and thrive on it when they fail to do well on the same mixture with water diluent. In nearly all cases where milk must be discontinued temporarily, dextrinized gruel will be found useful.

Whey has a value as a temporary substitute for milk, but as a steady diet has the disadvantages of peptonized milk in that it does not develop the motor function of the stomach.

Sterilization and Pasteurization of the infant's food have been strongly advocated on the ground that cow's milk contained innumerable bacteria while breast milk was free from them. Later investigations have shown that it is more the character of the bacteria present than the number, that cause sickness in infants. Baginsky has recently advocated feeding infants buttermilk and has reported 182 cases so fed. In preparing this food a pure culture of lactic acid bacteria was added and allowed to develop lactic acid enough to sour the cream. Bacterial counts of sour cream from which buttermilk is made have shown as high as 1,500,000,000 bacteria per c.c., mostly of the lactic acid class, and yet infants thrive on buttermilk.

The bacteria that produce poisonous products come from filth. These may gain access to the milk, or to the infant's digestive tract in the home, as is shown by infants being attacked who are taking the breast or condensed milk. Much of the ordinary milk supply does not seem to contain harmful bacteria. However, sterilization and Pasteurization have practical advantages in addition to destroying the harmful bacteria that may be present, and will always be necessary in hot weather unless milk quite free from bacteria is obtained and kept on ice until used. In the experiments in curding milk previously mentioned, the milk was slightly acidified *after* the rennet was added and it was the acid that caused the curds of cow's milk to shrink rapidly and become leathery. In hot weather it is difficult to keep the milk or food so that the lactic acid bacteria which are almost always present will not develop some acid. When such food is taken into the stomach the milk quickly curds with rennet, and the lactic bacteria at the body temperature rapidly produce more acid, which causes the curds to contract and toughen. After this contraction has taken place the curds become very indigestible and form a good culture field for any harmful bacteria present in the milk or digestive tract. In buttermilk enough acid has been produced to precipitate the casein, which will not then form a solid clot with rennet. Thus a small quantity of acid toughens the curds while a large quantity prevents their formation.

Pasteurization is useful in hot weather not because it makes the milk more digestible, but because it kills the acid producing bacteria which make the milk curds less digestible.

It should be remembered that Pasteurized milk a day or two old may cause vomiting and diarrhea as a result of the growth of putrefactive bacteria not destroyed.

*Art of Feeding.*—When it comes to the management of a particular case, there should first of all be taken into consideration the intelligence of the mother or nurse and their willingness to carry out instructions.

A child of nervous parents will require a great deal more care and attention to details than a child of laboring parents. The *method* of feeding employed in one case may have to be very different from that of the other; yet the problem is the same in both cases.

When starting a well infant in an intelligent family on artificial feeding, the plan of commencing with diluted top milk as previously mentioned will generally be successful. The increase in the strength of the food should be gradual and the infant should give evidence of being happy and contented, that is, sleep well, have good stools and gain in weight. Regularity in the hours of feeding should be insisted on. If the infant is nervous, efforts should be made

to keep it free from excitement as this will greatly interfere with digestion.

When the use of top milk is out of the question, whole milk may be diluted two to six times and one part of sugar added to 20 parts of food and the mixture Pasteurized or brought to a boil and then cooled. In summer time it may be best not to use top milk for any cases, especially if there is a tendency to vomiting. Where even diluted whole milk cannot be prepared properly, condensed milk is the only thing that can be employed, although it is not the best food from a nutritive standpoint.

Cleanliness of bottles, nipples and everything pertaining to the infant are important factors in successful feeding.

In the management of cases where there is much gastric or intestinal disturbance, much time and patience are required and it may be necessary to see the infant and examine its stools every day. The best plan is to stop all milk food and wash the stomach, as, according to Herter, much of the mucus that is mixed with the fecal matter comes from the stomach. Feed very thin barley water, a teaspoonful of barley flour to the pint, for twenty-four hours or until vomiting ceases. Then increase the strength of the gruel to one to two rounded tablespoonfuls of barley or rice flour to the pint and dextrinize. Keep on this for two or three days and then add *one* teaspoonful of plain or even skimmed milk to a two-ounce feeding; the second day try two teaspoonfuls of milk to two ounce feeding and so increase the amount of milk. Later the top 20 ounces from a quart of milk may be used for diluting and then the top 16 ounces. This will bring up the fats. Sugar should be added cautiously.

If one teaspoonful of plain or skimmed milk to a two ounce feeding is not tolerated the same quantity of condensed milk may be tried. If this succeeds, equal quantities of cream from bottled milk, and condensed milk should be mixed and diluted. The addition of the cream overcomes some of the objections to condensed milk which by itself is a one-sided diet, low in fats and proteids but high in sugars. Whey may be of temporary use in these cases.

A class of cases is seen in which the food is taken with indifference and while fairly well digested, does not seem to build up the infant. In this class of cases the use of mutton or chicken broth, beef juice with dextrinized gruel diluents, or anything that appeals to the appetite is indicated. Efforts should be made to vary the flavor of the food and so arouse interest in the bottle.

Constipation should be overcome by using oatmeal in making the diluent, and by giving well-cooked and strained prunes to increase the intestinal secretion in preference to increasing the quantity of fat so that it acts as a laxative.

Whenever there is a rise of temperature with a diarrhea, castor oil should be given and all milk stopped until temperature and stools are normal, when the feeding may be resumed as mentioned for difficult cases. That a great reduction in the death-rate from diarrheal diseases is possible by this treatment has been conclusively proven by Kerley.

## A CASE OF PANOPHTHALMITIS IN TYPHOID FEVER.*

BY W. WHITEHEAD GILFILLAN, M.D.,

OF NEW YORK;

FELLOW OF THE N. Y. ACADEMY OF MEDICINE; VISITING OPHTHALMIC SURGEON TO THE CITY AND FRENCH HOSPITALS; OCULIST TO THE SAILORS' SNUG HARBOR AND THE HOUSE OF REFUGE; ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, ETC.

PANOPHTHALMITIS is an inflammation of all the tissues of the eyeball. It may be caused by infection from without due to penetrating injuries or unsuccessful operations. This is by far the most frequent cause. It may also be produced by infection from within through embolism, septic substances from a focus of suppuration getting into the circulation and becoming arrested in the vessels of the choroid and other diseases. The case reported here is of the latter class.

Panophthalmitis is one of the most painful of eye diseases. Fortunately we do not observe it frequently. In the treatment of 20,000 cases in our eye hospitals about six or eight cases will be seen. Nearly all of these being due to the causes first mentioned. It is well we meet it no more frequently, as it is very destructive to the eye. The sight not only is lost, but also the shape, which results in a shrunken eyeball (Phthisis bulbi). The inflammation may extend to the meninges and brain and produce death. This is a rare occurrence however.

When the inflammation gets well established there is nothing that can be done to save the sight. Panophthalmitis complicating typhoid fever is a very rare occurrence. Less than a dozen cases have been reported.

The patient, a young man thirty-one years of age, entered the medical service of Dr. Van Horn Norrie at the City Hospital, Blackwell's Island, August 25, 1902. I am indebted to Dr. Norrie for his kindness in letting me report this case, and also to his house physician, Dr. H. M. Little, in giving me the full history and temperature chart.

The patient had complained of loss of appetite, pain in the abdomen, vomiting and diarrhea for the two weeks preceding his admission to the hospital. These symptoms continued. The temperature was 103° F., pulse 100 and respiration 28. Examination of the urine showed it to be alkaline. Specific gravity 1.015, and a small amount of al-

* Read before the Society of the Alumni of the City (Charity) Hospital, March 11, 1903.

bumin. The microscope revealed a few hyaline and granular casts. He was fairly well nourished but his cheeks were flushed and the expression apathetic as well as the mucous membranes being pale. The tongue was coated.

The left eye, the one which was subsequently affected by panophthalmitis, had no sight. This was due to an injury received some seventeen years before resulting in an occlusion of the pupil. The diagnosis of typhoid was made.

August 27, two days after admission, a test was made of the blood. It showed Widal's reaction for typhoid in dilution of 1 to 20: leucocyte count 3,000.

August 29. Patient was very delirious during the past night and quite irrational this morning. Leucocyte count to-day, 2,600.

August 31. Abdomen distended and tympanitic.

Sept. 1. Pulse slightly irregular and weak.

Sept. 2. Tympanitis has disappeared. Pulse much improved.

Sept. 5. This is the twenty-sixth day of the disease. To-day the outer part of the conjunctiva of the left eye is somewhat swollen and edematous: no discharge: a saturated solution of boric acid ordered every four hours, and ice applications every other hour to the eye. At five o'clock in the afternoon the eye was much worse. Lids, the upper one especially, very much swollen and edematous, with considerable redness of the skin. The conjunctiva is intensely reddened and likewise very edematous. The cornea dull with a diffused cloudiness. The eyeball is markedly protruded (exophthalmus): no discharge.

Sept. 6. Eye still further protruded and the tension is very much increased.

Sept. 9. The condition of the eye is the same except for a slight mucopurulent discharge. I was called in to-day to see the case and the diagnosis of panophthalmitis was made: patient very weak and unconscious. Treatment changed to hot applications, for fifteen minutes every half hour, to the eye.

Sept. 11. Eye somewhat improved. Discharge increased and more purulent in character. A small opening in the anterior sclera allows the discharge to escape.

Sept. 13. Eye much better; swelling of the lids much less; discharge continues free.

Sept. 16. Swelling of the lids entirely disappeared; eyeball beginning to contract; discharge less.

Sept. 29. Patient sitting up; discharge has stopped.

Oct. 3. Eye much shrunken; treatment discontinued. Eye is now a phthisical one.

In regard to the typhoid condition, the patient ran a regular fever course as the temperature chart will show. The panophthalmitis ran a rapid course. The duration generally being about six weeks to two months, whereas in this case it took only a month.

Fortunately for the patient the disease affected the eye which already was blind, otherwise he would have been in a sad plight. I do not think the injury seventeeen years before had left any condition which would predispose to this disease.

It will be noticed that this complication did not begin until the twenty-sixth day of the fever. By this time the height of the fever had been passed.

The patient was treated by the cold bath method for his fever and was discharged cured from the hospital the last of October.

24 West Fifty-ninth Street.

## MEDICAL PROGRESS.

### SURGERY.

**Diminution of the Sternocricoid Distance.**—In the course of examination of a patient who had twice suffered injury to the cervical portion of the spinal column, with a resulting cervicodorsal kyphosis presumably compensatory to the subluxation or fracture of one of the vertebræ, A. Fasquelle (Rev. de Chir., June 10, 1903) discovered a decided lessening of the distance between the superior border of the sternum and the cricoid cartilage. Inasmuch as radiography throws very little light upon affections of the spinal column, the author believes that measurement of the distance between the cricoid and sternum may be a valuable aid to the diagnosis of fracture, dislocation or sinking of the cervical portion of the spinal column. Out of 100 patients subjected to this test, he found the average space between the inferior border of the cricoid and the top of the sternum to be 45 mm.; whereas in the patient with the abnormal spine, the distance was but 15 mm.

**Adrenalin in Cancer.**—By reason of the vasoconstriction which it effects, adrenalin is capable of modifying the vascularization of cancerous tumors, writes C. Fiesinger (Jour. des Prat., April 25, 1903). In cancer of the rectum, painting twice daily with from 30 to 100 drops of a 1-in-1,000 solution of adrenalin in a tablespoonful of water decreases the accompanying rectitis, may check the discharge and brings about a temporary diminution in the size of the cancerous growth. External, ulcerated cancers become pale, decrease in volume, the hemorrhage may be checked and the progress of the affection is stayed for a time by the use of this remedy. Combined treatment with adrenalin, quinine and beer yeast is, in the author's opinion, distinctly serviceable in the prevention of recurrence after ablation of cancerous tumors. He reports the case of a woman operated upon in 1901 for cancer of the uterus, in whom, the operation being incomplete, a recurrence was expected. During 1901 and 1902 the patient was given quinine hydrochlorate 0.25 in cachet before breakfast and dinner, for five days, and a teaspoonful of beer yeast before meals the next five days; the two remedies being alternated thus for a month, at the end of which time treatment was suspended for five days and resumed in the same order. In 1902, adrenalin was added to the treatment, 5 to 10 drops of the 1-in-1,000 solution being given on rising and retiring the days on which the beer yeast was given. At the present writing, the patient continues to enjoy excellent health. In another case, operated upon three times for cancer of the breast, which recurred very shortly after each operation, this treatment was given, with the result that seven months have elapsed without a reappearance of the cancerous growth.

**Calcareous Osseous Atrophy Following Traumatism.**—The importance of radiographic examination in the study of the remote effects of fractures and contusions is urged by A. Imbert and J. Gagnière (Rev. de

Chir., June 10, 1903) in order that the necessity for therapeutic treatment which would stimulate skeletal nutrition, may not be overlooked, and that the significance of such symptoms as pain, impaired function, etc., may be cleared up. Osseous affections of a certain duration are indicated radiographically by changes in transparency or form of the affected bone, or both. Thus syphilis or tuberculosis of the bone is accompanied by change of form and increased transparency; while in osteomyelitis the opacity of the bone to the X-rays is increased. On the other hand, osseous changes following fracture or even occcasionally traumatism of the soft parts alone, are indicated by increased transparency to the X-rays without change in the form of the bone. This transparency may be uniform or broken by opaque spots. In the authors' experience, there seems to be no relation between the site of the fracture and the resulting osseous atrophy, and of two fractures surgically identical as to site, mechanism of production and displacement of the fragments, one may be followed by osseous atrophy, while the normal mineralization of the bone may be preserved in the other. After compound fractures followed by suppuration, osseous atrophy is usually very pronounced and may extend some distance above and below the fractured point. Osseous atrophy is the rule when, after a simple fracture, consolidation or calcareous infiltration of the callus is retarded. The earliest date at which the existence of calcareous atrophy may be detected by the X-rays is four and a half weeks; and in one of the author's cases, repeated examination with the X-rays failed to reveal osseous atrophy till four months had elapsed.

**Subdiaphragmatic Abscess of the Liver.**—A method by which posterosuperior abscess of the liver may be reached and surgically treated without risk of contamination of the pleural or peritoneal cavities has been devised by P. Mendes (Rev. de Chir., June 10, 1903). He describes the operation as follows: The patient being placed upon the left side, an incision 12 mm. long was made along the ninth rib, starting from its junction with the cartilage. Two incisions, having their origin at the seventh intercostal space, were made to meet the two extremities of the first. The flap thus made was dissected and laid back, the eighth and ninth ribs laid bare, denuded of their periosteum and resected (the former to the extent of 8 cm., the latter 10 cm.) without injury to the pleura. With the finger, the parietal layer of the pleura was then stripped from the ribs below the incision as far as its reflection upon the diaphragm. Then raising, as far as possible, the cul-de-sac of the pleura, an incision was made in the diaphragm which gave egress to 423 gm. of pus. Two large drains were then inserted in the wound, these being removed upon the ninth day, and the wound was completely closed within a month. The author gives to his method the name parapleural transdiaphragmatic.

**A New Process of Exenteratio Bulbi and Ocular Prosthesis.**—The difficulty experienced by oculists in the substitution of a foreign body for the enucleated eyeball is due to the scanty support for such a body, writes A. Ferrar (Gazz. Siciliana di Med. e Chir., May 28, 1903). He describes a method of enucleation and prosthesis which he has successfully used in several cases and which he believes to be free from the objections of other methods. This consists in the preservation of the entire ocular capsule, that is, the cornea and sclera; the contents thereof being emptied through a linear incision of about 2 cm. made in the upper segment of the bulb parallel with its equator and about 4 mm. from the sclerocorneal junction. After the capsule is entirely emptied, the margins of the wound are approximated and sutured; one suture at the center of the wound being left untied so that a small aperture remains for the introduction of the point of a syringe filled with liquid paraffin. The capsule is completely distended with this substance, so that an artificial eyeball is formed, over which may be fitted a glass eye, capable of being moved naturally, owing to the fact that all the muscles are intact and their normal insertions are preserved. To check hemorrhage and avoid the danger of entrance of the paraffin into the central artery of the retina, the author proposes that a few drops of a 1-in-1,000 solution of adrenalin be instilled into the capsule prior to injection of the paraffin.

**Ignition of Ether Vapor by an Electric Light.**—Every surgeon thoroughly appreciates the danger of an open lamp anywhere near ether vapor but it is generally supposed that an electric incandescent light is perfectly harmless. To be sure, accidents from this cause are extremely rare, but D. H. Murray (N. Y. Med. Jour., June 27, 1903) reports an instance in which the ether vapor about a cone by which a patient was being anesthetized was ignited when an electric light was turned on nearby. The patient s hair was badly singed but no serious injury resulted. As there was no exposed fire or blaze in the operating room at the time it was concluded that the ignition resulted from the spark in the electric light, made when the contact took place in turning on the light. It is a possible danger worth remembering.

**Splenectomy and Talma's Operation in Ascites of Malarial Origin.**—Cases of excision of the spleen for various indications are becoming quite frequent, and Roeser in his last work on diseases of the spleen presents statistics of 200 operations. Among the indications we find prolapse of the spleen, rupture, various traumata, wandering spleen, abscesses and various new formations, hemorrhage, enlargement from malaria, splenic anemia, and even leucocytosis, and amyloid degeneration of the organ; finally splenectomy was recommended of late in Banti's disease. Last year Tausini hit upon the original idea of adding to a splenectomy Talma's operation, namely, remove the suspected focus of infection and create lateral paths for the disturbed abdominal circulation. Finkelstein (Roussky Vratch, No. 22, 1903) performed successfully a similarly combined operation for an enlarged spleen with considerable ascites of malarial origin. The patient was a native of a malarial district of Caucasus, with a history of malarial infection of twelve years' duration. For the last thirteen months she began to suffer from a gradually increasing pain and swelling in the left subcostal region; to this were added considerable dyspnea, frequent and severe vomiting, and complete anorexia. The largest circumference of the abdomen was 116 cm. Operation performed three months after admission to the hospital (other measures of treatment having proved ineffective), and proved successful, as the pains disappeared, the abdominal circulation became equalized, and nutrition improved. The author considers as the most important element of the success the performance of Talma's operation whereby collateral circulation was established in the abdomen, and thus an end was put to the severe ascites. Postoperatively it is interesting to note that for the first ten days there was a rise of temperature in the form of a non-intermittent fever, later on this gave way to a series of typical malarial intermittent attacks, which finally yielded to internal administration of arsenic and to hypodermic injections of quinine. The author thinks, together with Michayloosky and Jonnesco, that the extirpation of a "malarial" spleen does not always rid the patient of malaria, and the attacks of malaria are not less severe in patients without spleens than in those with healthy organs. The prognosis of the operation may generally be considered as favorable. Février found out of 86

operated cases of extirpation of malarial non-wandering spleen 17 fatal issues. Out of 16 cases Michaylоosky lost but one, and that was due to an accident (pneumonia with pleurisy). On the other hand, cases of extirpated spleen for other indications run a more favorable course, as when the operation is performed for movable, namely, wandering (floating) spleen, or one that became enlarged because of anemia; in Banti's disease 13 cases of operation gave 3 deaths. It is the opinion of a great number of observers (and among them very many Russians) that the removal of the spleen is not attended by any marked or vital disturbances of nutrition or other functions of the organism. It is doubtless that with more positive and exact indications demanding this operation, a minimum of fatality will be reached.

## PEDIATRICS.

**Feeding of Older Infants.**—From the ages six to twelve months most infants are sufficiently developed to be able to digest cereal foods. Even when a high milk formula cannot be digested it is found that they may thrive on an easily digested and nutritious cereal mixed diet. W. M. HARTSHORN (Med. Rec., June 27, 1903) reports that in the Nursery and Child's Hospital during the past few months all babies over seven months, both artificially fed and nursed, whose digestion seemed able to stand extra feeding, were given some stronger food and it was found that of flaked rice, cream of wheat, oatmeal gruel, farina and bread and milk, the latter proved the most satisfactory. This was prepared from stale bread from twenty-four to forty-eight hours old. The pulp was soaked in boiling water until thoroughly softened and the water was poured off and a cup of milk added. This was then boiled for three or four minutes. After being sweetened and cooked sufficiently it was fed to the baby. At first it is given in teaspoonful doses but later it is increased until they may get from two to three ounces daily in feedings of not more than half an ounce at a time. Older children receive plain bread and milk once daily. In the morning they generally get farina with milk. At noon boiled rice with meat broth poured over it. Fruits are given in season. The weight charts are excellent evidence of the advantage of this extra feeding.

**Examination of Milk by the General Practitioner.**—Milk with an acidity of over two-tenths of one per cent. is not fit for drinking purposes. H. L. K. SHAW (Ann. of Gyn. and Ped., May, 1903) determines this either by a simplified titration method or by alkaline test tablets. The next step is to obtain its specific gravity. The author does this by means of a small Quevenne lactometer constructed with a thermometer. This is graduated from 1.020 to 1.050 and requires a little over half an ounce for a reading. The specific gravity of mother's milk averages 1.030 and is lowered by an increase of fat and raised by a high percentage of proteid. If the specific gravity of cow's milk is less than normal (1.029 at 60° F.), one of two things may be suspected. Either the milk contains an unusual amount of cream or the milk has been watered. If, on the other hand, the specific gravity is higher than normal and the percentage of fat is low, it is fair to assume that the milk has been skimmed. The percentage of fat is obtained in many ways, but the writer prefers the Babcock method. The percentage of sugar varies but little and its estimation is not required in an ordinary examination. The quantitative Fehling test employed in urinalysis may be used for this purpose. The total solids can be determined from the corrected specific gravity and the percentage of fats. The Babcock method consists of dividing the specific gravity of the milk by four and adding to this one-fifth the per cent. of fat. This will give the solids not fat, and adding the per cent. of fat to this product the amount of total solids is obtained. The amount of proteid can be estimated approximately by subtracting the percentages of fats, sugars and salts from the total solids. The Hehner and phloroglucin tests are recommended for the detection of formalin in milk.

## THERAPEUTICS.

**Calcium as a Hemostatic.**—The differences of opinion as to the influence of calcium in increasing the coagulability of the blood seem to have been adjusted by the experimental work of T. SILVESTRI (Gazz. Osped., June 14, 1903), who finds that the influence of the drug depends upon the degree of concentration; large doses retarding coagulation while small doses increase it. In a series of experiments with the blood of sheep and calves it was proven by him that the addition to the blood in vitro of increasing doses of calcium chloride to the limit of 12 mgr., brought about progressive hastening of coagulation and a more retractile clot. Twenty milligrams represented the maximum dose from which coagulation was unchanged and beyond this limit, clotting was retarded. Subcutaneous injection, in a dog, of 40, 55, and 65 c.c. of a one-per-cent. solution of calcium chloride was followed by coagulation of blood, drawn from the femoral vein of the animal, in 15′, while 20, 25 and 30 c.c. induced clotting in 13′. Finally, blood from the cephalic vein of a patient subject to epistaxis was examined; the specimen coagulating in 12′, while administration of calcium hypophosphite per os gm. 7 daily induced coagulation in 9½′ and gm. 4 daily produced clotting in 9′.

**Treatment of Whooping-cough.**—Although this is a self-limited disease and seldom fatal, yet it becomes frequently a very distressing condition and on account of its interference with proper nutrition it demands most serious consideration. T. W. KILMER (N. Y. Med. Jour., June 20, 1903) believes that the medicinal treatment which has proven the most efficacious is that recommended by Dr. C. C. Kerley and consists in the alternate use of an antipyrine mixture and quinine. A child, two years old, is put on the following:

℞ Sodium Bromide..... gr. iij
Antipyrine ..... gr. j
Syr. Ipecac..... ♏ iv
Water .....q.s., ad. ℥i

This constitutes one dose and is given every two hours for three or four days. The child is then given three grains of quinine sulphate every three hours for three or four days and is then put back on the antipyrine mixture. The only drawback is the possibility of upsetting the stomach with the quinine. His greatest success in the treatment of this disease has been obtained, however, by the new application of an old principle by which the spasms are greatly controlled and the vomiting usually entirely eliminated. A stockinette band is placed upon the baby extending from the axillæ to the pubis and fitting snugly. Two shoulder straps are used to prevent the band from slipping down. Upon this stockinette band a single width of elastic bandage is sewn, extending entirely around the body and covering the abdomen. It is sewn on when very slightly on the stretch and if not successful should be drawn a little more snugly. This simple measure will almost always entirely control the vomiting seen especially in nurslings. Such a band, furthermore, when applied around the chest is of marked advantage in aborting the paroxysmal stage and the two bands may thus be combined. The only disadvantage of the method is that in some cases a slight eczema is caused upon the underlying skin, but this readily clears up as soon as the band is removed.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Tuberculous Antitoxin Per Os.**—Following up the work of Italo, who obtained a certain increase in the antitoxic power of the blood-serum of patients by administering to them tuberculous antitoxin by mouth, F. FIZARI (Gazz. Osped., June 14, 1903) sought to determine whether the formed elements of the blood of animals immunized to tuberculosis were endowed with antitoxic properties and whether such elements, given by mouth, could impart resistance to tuberculous toxins. To this end, the clot of blood taken from immunized horses and cows was dried and reduced to powder, and 3 gm. daily administered to rabbits. The agglutinating power of the rabbits' serum was tested before and after a course of treatment with the powder, with the result that a marked increase in agglutinating power was seen after the treatment. As to the increase in antitoxic power, the following results are recorded: After eighty-five days' treatment, the rabbits were injected with mortal doses of tuberculin. Half the animals subjected to such injections lived for thirty-six hours while the control animals survived but twelve to sixteen hours. The remaining number survived and were in good health at the time of writing.

**Callus Formation in the Fractures of Osteomalacia.**—The manner in which the callus is formed in fractures during this disease has rarely been discussed in the literature of the subject and the views of the various authors differ greatly. I. BECKMANN (Deut. Archiv f. klin. Med., Vol. 76, No. 1) publishes two further cases from which some interesting results are drawn. The Roentgen rays were employed in the author's two cases and although the skiagraphs were taken several months after the injury, no signs of any callous formation were in evidence. In one case there was a very faint shadow around a fracture of the bones of the forearm, around which some degree of union seemed to have taken place, but the very slight deposit of lime salts permitted the rays to pass through without interference. In the other case the fragments were not in apposition, and the picture taken five months after the injury, showed absolutely no evidence of repair. The author thinks that the reason that in one case there seemed to be formation of a functional callus, but without the presence of lime-salts, while in the other there were absolutely no traces of a callus, is due to the fact that the osteomalacia in the former case had not advanced as far as in the latter. For it is a well-known fact that the further along the disease is advanced, the less likely is repair apt to take place. These observations also show that the X-rays afford a very effective means of gauging the stage to which the process has advanced, for in the first case the bone presented a spotted or marbled appearance, while in the other nothing could be detected of any bone structure. This may be of great value in doubtful instances.

**Eberth's Bacilli in the Roseola of Typhoid Fever.**—The eruption of typhoid fever is known as one of the important symptoms of the disease. As far back as 1880, Eberth, and after him Koch and Gaffky, found on investigation that the roseola of typhoid fever is the direct result of the poisonous element of the disease. In 1899 Neufeld substantiated the formerly expressed opinions of Neuhaus and Thiemisch, to the effect that the blood of the roseola contained a special kind of bacteria that cause the appearance of the eruption. These spots shelter, as it were, a certain number of viable bacilli which are here protected from the bactericidal power of the circulating blood. The investigations of Neufeld were later on carried out with the same results by Curshman. KAZARINOFF (Roussky Vratch, No. 22, 1903) conducted his experiments on 15 undoubted cases of typhoid fever, among whom 2 had the disease in a recurrent form, and in these the roseolæ were investigated twice. Omitting his methods of examination we can only stop here on the following results obtained by him: In the lymphatic vessels of the excised roseolæ there are found variously grouped a number of closely lying typhoid bacilli; the blood-vessels are free from them; the tissue containing the bacilli is considerably swollen, although not to the dimensions claimed by Fränkel; the number of cells is increased, but not through the addition of white corpuscles. No necrosis of the tissue was anywhere observed by the author. It thus becomes evident that in the eruption of typhoid fever we may see a process depending on inflammation and infiltration of the corium due to the emigration or rather transportation of the typhoid bacilli through the lymphatic vessels. In doubtful cases of febrile disease, when a positive diagnosis can not be established, it may be of some value, as suggested by Curshman, to examine the contents of a roseola, if such be detected.

**Experimental Tuberculosis in the Dog and Resulting Toxemia.**—The course of experimental tuberculosis produced in dogs by endovenous injections of virulent cultures of Koch's bacillus and the toxemia following such injections has been studied by CASAVECCHIA (Gazz. Osped., June 21, 1903). After a varying length of time the animals were killed, and examination revealed entire absence of tuberculous infection of the glands or viscera, save in the lungs, where a miliary bronchopneumonia was found; the bacilli having been arrested in the pulmonary circulation and destroyed, as proven by bacteriological examination. That a grave toxemia resulted from these injections was shown by the condition of the animal shortly after treatment, as well as by the marked increase in the hemolytic power of its serum toward the blood of rabbits, as compared with the hemolytic power shown by the same serum when the animal was in its normal state. In those animals which were allowed to live a greater length of time, a gradual improvement was seen, and examination of the lungs showed regression of the pathological process, from which the author concludes that with the destruction of the bacilli, elaboration of tuberculous toxines ceased, and as a result toxemia was eliminated; a like sequence occurring in those clinical cases which undergo spontaneous cure.

## PHYSIOLOGY.

**Influence of the Contents of the Large Intestine on Strychnine.**—It is known that small quantities of strychnine added to the contents of the cecum and colon of normal rabbits, cannot be detected by Haines' method. In a number of control experiments, however, in which a smaller quantity (1 mg.) was mixed with gastric contents, liver, crushed brains or urine, the strychnine could be detected by the same methods. The conclusion was therefore drawn, that there was some substance present in the colon and cecum of normal rabbits which interfered with the methods of detecting the drug now at our disposal. The same author, W. SALANT (Am. Med., June 27, 1903), has now made some further expirements, and believes that the inability to find the strychnine in the first instance was due, not to anything in the intestinal contents, but to a faulty method. He explains this as follows: The various methods usually employed for the detection of the drug are very elaborate and require numerous manipulations. The solution is subjected to several filterings and reagents, before the alcohol is ready for the final tests. As only small quantities are present, the loss of even a minute portion may influence the result. The success of the same method in separating

strychnine from the mixtures of liver, brains, urine, etc., may be explained by the fact that organic impurities were not so numerous and filtration much better, therefore the manipulations were reduced in number. This may explain why in many cases of strychnine poisoning the alkaloid has not been found. The author outlines a simpler method for making the tests, by which he has succeeded in proving the presence of the drug in the intestinal contents, where the other methods had previously failed.

**Contact-phenomena in Spermatozoa.**—The motion of the spermatozoa in the uterine canal upward toward the openings of the Fallopian tubes, is supposed to be in response to the mechanical stimulus of the cilia lashing in the opposite direction. J. Dewitz (C'blatt f. Physiol., May 23, 1903), who was the first to discover thigmotactic phenomena in the animal kingdom, proves that spermatozoa do respond to contact-stimulation. By suspending minute globules of vaseline in physiological salt solution, and adding to the latter active spermatozoa of the frog, he observed that they moved freely in all directions through the solution, but never through the thin drops of vaseline, moving around or away from them, as if studiously avoiding this kind of medium. This peculiar phenomenon can be explained only on the basis of contact-stimulation.

**The Influence of Alcohol upon Proteid Metabolism.**—That alcohol can be utilized by the organism like fats and carbohydrates, and can exercise the same proteid-sparing power as the latter, has been established by many observers, and is confirmed by the researches of R. Rosemann (Pflüger's Archiv, Vol. 94, Nos. 11 and 12). The latter shows, however, that under certain conditions, alcohol manifests regularly a proteid-destroying power. This is seen in cases not habituated to alcohol, but also in those accustomed to alcohol at the beginning of its administration, and also most probably in cases where the food has a low caloric value. At any rate, this unfavorable action of alcohol on proteid metabolism seems to be, in the majority of cases, a transient phenomenon, for its proteid-sparing power soon appears. This explains the erroneous conclusions drawn from the earlier investigations in this field; the experiments were of such short duration that they only revealed the first stages of the action of alcohol on the transformation of proteids, which in all cases were unfavorable.

**Poikilothermism in Rabies.**—It has for a long time been known, according to J. O. U. Barratt (Jour. of Physiol., June 15, 1903), that in animals suffering from rabies, the body temperature, which is usually described as being slightly raised toward the end of the incubation period, subsequently becomes subnormal. Rabbits at the close of the disease are poikilothermic, the body becoming cold and the rectal temperature during the last twenty-four hours of life being within a few degrees of the room temperature. This phenomenon is to be attributed to a paralysis of the heat-regulating mechanism. During this stage the respiration-rate and the heart-rate are retarded.

**Meat Diet and its Relation to Gout.**—A careful review of the experiments of the earlier investigators in this field, precedes the description of the researches and results of M. Kochmann (Pflüger's Archiv, Vol. 94, Nos. 11 and 12). Pflüger showed in 1900 that an exclusive diet of horse-flesh produced in dogs severe diarrhea. He succeeded in isolating, to a certain extent, the constituent producing this deleterious effect; he found it present in the broth of the meat, could not precipitate it by means of alcohol, but could obtain an ethereal extract. At this time Kionka showed that he could produce a genuine arthritis urica in hens by an exclusive diet of meat lasting for five months. Others before this had produced gout in birds in various ways: Ebstein, by the injection of chromic acid; v. Kossa, by the administration of oxalic acid, phenol, etc. The microscopic changes in the organs of hens made gouty by methods such as those of Kionka, were studied by Bannes, with the following findings: retention of urates in the liver, kidneys, spleen and serous membranes; degenerative processes in the liver, kidneys and spleen; necroses and cloudy swellings of the epithelia of the larger parenchymatous organs; and finally that there is microscopically a difference between gout induced by renal poisons, such as chromic acid, and that induced by an exclusive meat diet. The above results inspired the author to investigate the problem as to whether any pathological changes could be found in mammals after an exclusive diet on meat. The animals experimented on were dogs. Three of these animals after being fed for forty days on meat alone, were killed by opening the carotids and immediately subjected to autopsy. They all showed fatty degeneration of the kidneys and liver, differing qualitatively in each case. The clinical history of these animals was as follows: As regards weight, all three presented marked changes, sometimes increasing, sometimes diminishing, but the end-weight being not very different from the initial-weight. The general condition was always good. The urine sooner or later contained albumin. Although no casts were found, the state of the urine indicated a nephritis. The animals were markedly constipated. The autopsy revealed in all the cases an acute or a subacute nephritis, a cloudy swelling of the liver-parenchyma, and a pigment deposit in the spleen. The author maintains that although he was not able to produce gout in dogs, as Kionka had in hens, yet his results show some analogy to the clinical and pathological manifestations of human gout, and that he has proved a direct relationship between an absolute or almost absolute meat-diet and the etiology of gout. He alludes, in this connection, to the frequency of gout among the beef-eating Englishmen, to the increased elimination of uric acid following a superabundant meat diet, and to the fact that only a part of the uric acid is eliminated through the kidneys. The greater part is destroyed, and according to Wiener, in different animals is destroyed in different parts of the body. In the dog and perhaps also in man, a part of the uric acid is broken up in the liver; in the cow, a portion is destroyed in the kidneys, and in all mammals the muscles take an important part in its destruction. Any degeneration, therefore, of the liver and kidneys would interfere with the destruction of uric acid. Moreover, lack of exercise would impair muscular activity in this direction. The diseased kidneys would at the same time be unable to do their share in the excretion of uric acid, with the result that this substance, accumulating in the body in certain localities, would give rise to the pathological and clinical picture of gout. A further support to this hypothesis is seen in the fact that the uric acid arthritis develops gradually, that degenerations of the liver and kidneys are found in many cases of gout, and that all those influences that would cause degeneration of the kidneys, liver and muscles would favor the appearance of gout. Of these influences may be mentioned a meat diet, either exclusive, or nearly so, chronic alcoholic poisoning, and chronic metal-intoxication, particularly that of lead.

# The Medical News.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## THE LATEST WORK IN YELLOW FEVER.

It should surely be a source of national pride, when we view the fact, that all of the important discoveries concerning the cause and propagation of yellow fever have been the contributions of American scientists.

Sternberg's initial work upon the cause of this disease first showed that it was not due to a bacterial or vegetable parasite, and his experiments thus cleared the field for subsequent investigations.

The next milestone was reached when Surgeon Carter of the Marine Hospital Service distinctly showed that the disease was not contagious by personal contact, but that the spread of the epidemic depended on "place infection." He also brought forward the distinction between the intrinsic and extrinsic periods of incubation of the disease, which paved the way for the mosquito work of Finlay, Carroll, Reed and Agramonte.

The fact that the mosquito (*Stegomyia fasciata*) transmits the infection of yellow fever is a most valuable addition to our knowledge of the disease from a practical standpoint. It has made the suppression of epidemics a comparatively easy task, and has placed land and maritime quarantine measures upon a practical basis.

The report of Working Party No. 1 of the Yellow Fever Institute of the United States Public Health and Marine Hospital Service, about to be issued, now advances the subject one step higher by clearly showing the phases of development of the parasite causing yellow fever within the body of the intermediate host, *i.e.*, the *Stegomyia fasciata*.

The Working Party consisted of Doctors Parker, Beyer and Pothier, who spent the summer at Vera Cruz, where the prevalence of the disease gave them abundant opportunity for study and painstaking research. They demonstrate, with the utmost clearness, the various phases in the cycle of development of the parasite, from the stomach of the mosquito—which has bitten yellow fever patients—to the salivary gland.

Both the Yellow Fever Institute and the Working Party are to be commended upon the fact that they do *not* claim that the parasite in the *Stegomyia fasciata* is the cause of yellow fever; although from its relation to the disease, and from the fact that the parasite cannot be found in mosquitoes that have bitten other fever cases, the inference is very clear, that the cause of yellow fever in its sexual stage, has at last been discovered in the mosquito host.

The Yellow Fever Institute was founded in 1901, by Surgeon-General Walter Wyman, and its publications and results achieved have clearly justified the thought and work he has devoted to its organization and progress. The object at the Institute is to study yellow fever in all of its phases, until the menacing scourge is thoroughly understood in every detail.

The results of the labors of Doctors Parker, Beyer and Pothier must of course be corroborated, but we feel certain that since they have shown the way, others will have no trouble in attaining the same results. Those who have seen the slides and preparations of the mosquitoes that they have brought from Vera Cruz, are convinced of the importance and correctness of their findings. It now remains to find the parasite in the blood or tissues of human beings.

The conclusions of the Working Party, as given, are as follows: (1) That the bacteriological examinations of the blood of cases of yellow fever during life, and the blood and organs at autopsy, performed immediately after death, in uncomplicated cases, is negative; (2) that *Stegomyia fasciata*, when contaminated by feeding on a case of yellow fever, forty-one and a half hours after the onset of the disease, and subsequently fed on sugar and water for twenty-two days can

produce a severe attack of the disease in a non-immune individual. (3) That *Stegomyia fasciata* contaminated by feeding on a case of yellow fever, and after varying periods killed, sectioned, and appropriately stained, presents with regularity a protozoan parasite, the *Myxococcidium Stegomyiæ*, that can be traced through a cycle of development, from the gamete to the sporozoite. (4) That *Stegomyia fasciata* fed on blood from a case of malarial fever on normal blood, or artificially fed, does not harbor the parasite indicated in conclusion third.

These findings are not only very interesting, but are of the greatest importance in the elucidation of the true nature of the disease; and if they are corroborated by further examinations, and if the parasite is definitely located in the human body, we can feel that the problem of its etiology has been solved and that the epidemics in the future can be easily controlled.

---

## WHAT IS GOUT?

"From Sydenham's day to our own—to penetrate no further into the past—we have not failed to talk about gout; how much more do we know of it than we did?" So writes Clifford Allbutt in a charming introductory essay to a discussion on gout in the July number of the *Practitioner*.

There is rich material in this number—T. B. Futcher writes on the "Occurrence of Gout in the United States;" Alexander Crombie, on "Gout in the Tropics," and T. S. Toogood on "Gout as it Occurs Among the Poor." Samuel West treats of the "Relation of Gout to Granular Kidneys and Lead Poisoning." Alexander Haig rides his uric acid theories in discussing the "Causation, Prevention and Treatment." J. Walker Hall writes on "Metabolism in Gout and the needs for combined investigation." "Treatment" is discussed by Sir Dyce Duckworth, Arthur P. Luff and Gilbert A. Bannatyne, while F. J. Poynton reviews the "Recent Literature of Arthritis" and comments thereon.

Futcher shows that for the United States gout is not a common disease, but nevertheless it is not as infrequent as many physicians have been led to suppose. Thus, taking Dr. Osler's words as a basis of comparison, he finds that in the last fourteen years—May 15, 1889, to May 15, 1903—there were 41 cases of gout out of a total of 15,697 admissions or an incidence of .26 per cent., whereas in St. Bartholomew's in London during the same time there were 124 cases admitted in a total of 33,356 admissions, or an average of 0.37 per cent., thus making only one-third more for London. Baltimore, nevertheless, Dr. Futcher writes, has probably more gout than almost any other large city. One of the reasons for the supposed comparative infrequency in the disease, says Dr. Futcher, is the failure on the part of the profession to recognize it. It is to be regretted that Dr. Futcher did not go outside of the Johns Hopkins Hospital for his statistics.

In the tropics Dr. Crombie thinks that the disease is much less frequent, particularly in India, and in other hot climates, than it is in Europe among the same class of patients. It is rarely met with in hospital practice in India.

Poverty being a relative term, Dr. Toogood writes, that it might be better for the gout-stricken subject if he were just the amount poorer necessary to prevent his acquisition of malt liquor. He doubts if the really poor ever develop gout; those with gout among the poor are poor because of their habits. From forty to fifty are the favorite years of incidence, although some patients are but thirty-five years of age when involved. Occupation does not seem to play any rôle, although unaccustomed walking often induces attacks. As to causation, he holds that the consumption of malt liquors is the chief if not the only cause of the production of gout. Wine and rich food are not known among the poor.

It cannot be said that Dr. West's contribution assists us in ascertaining the real relation of gout to lead poisoning.

Dr. Haig still assumes that gout is a uric acid disease, not a "diathesis," but a poisoning; in fact, he is so bound up in his theory as not to see many of the important recent lights shed upon the chemical metabolism of gout by other workers—notably from the continental laboratories. He still believes it a diet disease due to poisoning by flesh and tea. Dr. Toogood tells us the poor have gout from malt liquors and do not know what rich food is like.

Dr. Hall approaches the subject of metabolism in a more modern and, to us, enlightened manner. He takes up, in turn, the metabolism of the various foodstuffs in relation to the disease, devoting particular attention to the nucleins. He points out the futility of coming to conclusions from the work that has thus far been done on gout and suggests the formation of a joint commission to take up the various complicated factors. Isolated work is economic loss and thus far has led to erroneous and one-sided doctrines.

Writing on the subject of diet, Sir Dyce Duckworth says that he does not regard the disease as a purely humoral one but one of neurohumoral pathogeny. If it is necessary for observers to show uric acid poisoning in all cases he says "such pedants will have to wait long if they insist on this evidence."

He is of the opinion that many of the methods of handling gout are founded mainly on the treatment of the supposed causes of the disease and not for the treatment of the patient. Thus the patient is disregarded and everything is seen, as it were, through uric acid spectacles. He ridicules, and justly, we believe, the old saws about red meats being prohibited but that white meats, fish and game are allowed. Beef being condemned and mutton allowed, and a host of other imbecile suggestions that still hang on in fairly reputable text-books on dietetics.

With reference to animal food generally, he says it may be declared not only harmless but beneficial to gouty persons, if taken in moderation. As far as vegetables are concerned, he knows of no reason why any of them should not be taken. Potatoes are not harmful, nor any plant grown under the ground. Alcohol is of great importance he believes. A small amount of good wine once a day will not hurt gouty patients, but most of them drink too much. Malt liquors particularly do harm to this class of patients. The chief feature, however, is to disregard general rules and determine the proper line of diet for each individual patient. Treat him and let the theories go.

Dr. Luff believes in the auto-intoxication theory—"the poisons being possibly the purins and other bodies, but of which we, at the present, know very little"—he thus modestly and wisely puts it. He insists on the irrationality of a routine treatment and outlines the general mode of treatment in acute, chronic and irregular cases, following well-known formulæ and not contributing anything new to our recent text-book methods. He still believes in the use of alkaline salts "for the removal of gouty deposits" but goes back on the much-lauded "lithium" salts. He contributes some new ideas on the preventive treatment of gout, extolling the use of guaiac resins and quinic acid salts.

Dr. Bannatyne praises the uses of baths, and devotes much time to the details of technic. Dr. Poynton closes the discussion with a comment and review on the recent literature of arthritis.

We know of no better summary of our ignorance than in the Notes by the Way of the editor of the *Practitioner* itself: "(1) We do not know how the excess of uratic matter is brought about, whether it is due to increased intake with the food, to increased formation in the body, or to deficient elimination by the excretory organs. (2) We do not know whether the uratic excess is the cause of the phenomena of the disease, or is a mere casual accompaniment of the perverted state of nutrition. (3) Similarly, we do not know in the case of the arthritic attacks whether the deposit of urate of soda is the cause or the effect of the local inflammation."

In all probability gout consists in a defect of metabolism whereby products deprived from cell-nuclei are not properly used up or excreted. These products may arise either from nuclear matter contained in the food, or from the natural wear and tear of tissue-nuclei: they are retained in the system, and a deposit of one of them—sodium biurate—in the joints sets up irritation there, and causes an acute attack of arthritis.

We must not be blind to the fact that in using "that blessed word" metabolism, we mean no more than the chemical side of life itself. All diseases are disorders of metabolism—in other words, perverted vital activity. Hence we practically come back to our original starting point—that gout is a disease which we do not understand.

## THE DANGER OF RAILWAY TRIPS TO HIGH ALTITUDES.

INDUSTRIAL progress creates new medical problems. Year by year the railways reach further and further into the wilderness and creep higher and higher to mountain peaks and valleys. Enterprising hotel managers, following in their sooty train, cap lofty summits with inn and lodge where formerly the lonely eagle perched unmolested. For the majority of people, this reaching out by man into Nature's distant quietudes is of great and distinct good. It takes him from the hum of his fellows to that rest which is essential to life.

But, while the majority of men profit, there is a very distinct, and a large and increasing class to the existence of which attention has, as yet, scarce been called, to whom in these mountain resorts there lurks the Angel of Death.

This is the season, when, from Maine to California practitioners are being called upon for advice as to the choice of regions in which to rest and recuperate from the winter's wrenching vor-

tex of dissipation and of work. The News believes it opportune to urge the possible danger of high mountain travel to all save the healthy and the young.

Physicians who are apt to be called upon to give advice in this matter, cannot do better than to read an article in the *Lancet*, June 20, 1903, by Theodore Zangger, late assistant physician, University Hospital, Zurich, Switzerland. He has, for a number of years, been in the position to observe the effect both of active and passive (railway) mountain climbing in the Alps. He concludes that it is a menace to the lives of elderly persons to ascend beyond 3,300 feet above sea level. Cardiac thrombosis and pulmonic embolism are the accidents to be feared. The seizures do not by any means always take place during the stay on high ground but often come on slowly or abruptly, one, two, or even three days after descent.

There are in this country, as compared with Switzerland, relatively few mountains which are clambered by railways to dangerous altitudes. The roads up Pike's Peak, Mount Washington and the Santa Fé, in New Mexico, as well as some of the transcontinental lines, both here and in British Columbia are exceptions. Outside of these there are, however, a number quite worthy of consideration.

Zangger considers that while under certain conditions 3,300 feet of ascent calls for precaution—in the case of patients with even slight arteriosclerosis the mountain railways up to 7,000 or 10,000 feet are positively dangerous. At this last level there is registered a fall of 200 millimeters in the mercurial barometer. This rarefaction of the air produces an increasing congestion of the pulmonary capillaries which is abetted by the sudden changes of temperature encountered at altitudes. Even when at rest, there is an increase of about 40 per cent. of the respiration volume as compared with the corresponding volume for the same person when on low ground. This in itself is a difficult proposition in the face of any emphysema whatsoever, and is easily seen to imply a marked increase in the work of the right heart. Many persons between fifty-five and seventy years of age consider themselves hale and hearty and are yet the subjects of advanced arteriosclerosis, emphysema and perhaps of cardiorenal involvement.

It may be useful to practitioners to be reminded that in Switzerland alone there are no less than nine railways which creep to an altitude of between 6,000 and 10,000 feet. Who has not heard of the Rigi Culm, 5,900 feet, of the Schynige Platte, 6,660 feet, of Scheideck, 6,470 feet, of Pilatus, 7,000 feet! These are, however all dwarfed into insignificance before the famous line which is being bored through the heart of the Jungfrau. This has, in the past ten days, reached its fourth station, which is at the 10,000-foot plane. It is probable that many American tourists will be unable to resist the delights of this unique journey.

So prominent had these problems become ten years ago that the Swiss Government actually refused to grant a franchise to Guyer-Zeller to build the road in the Jungfrau until scientists had fully considered the question of its relation to the public health. The well-known physiologist, Kronecker, of Berne, became a member of the committee, and its report (1890) was to the effect that it was not desirable to grant the franchise until the company had proved that such ascents could be made without detriment to health. Whereupon Guyer-Zeller immediately arranged, with the aid of forty-two guides, to carry seven people in chairs to the summit of the Breithorn. Kronecker and Sahli, of Berne, made observations on these subjects. Their conclusions were as follows: "Healthy people do not suffer from being conveyed without any exertion on their part to an altitude of some 12,000 feet, but as soon as any, even slight, muscular action is required of them, distressing, or even dangerous symptoms of circulatory trouble supervene." "Reduction of barometric pressure causes dilatation of the right ventricle." So important did the public health considerations seem to Kronecker that he made the following recommendation: "That a physician should be stationed at Scheideck (6,470 feet), who would examine any passengers, at their wish and expense, in order to dissuade them from the trip up the Jungfrau, should they be suffering from any serious affection of the heart or respiratory organs."

It will thus be seen that we have much to learn from the Swiss as to the choice of mountain resorts for a certain distinct class of people. As the honeycombing of mountains and the placing of inns at great altitudes grows more common, the general public, always eager for novelty, will rush to visit them. The course of the profession is clear. Only those travelers who can pass a rigorous cardiovascular examination should be allowed to undertake these delightful but dangerous mountain climbs.

# ECHOES AND NEWS.

## NEW YORK.

**New Health Regulations for Infants.**—The Department of Health has recently issued a circular on how to keep the baby well. The text is here given:

1. *Nurse it:* Nothing equals mother's milk for a baby food. If you cannot nurse the baby use *fresh milk*, which in hot weather has *been boiled* and prepared according to directions. (A circular of directions will be sent on application to the Department of Health). Nurse the baby part of the time, if you cannot nurse it all the time. Do not give it condensed milk or any prepared babies' food.

2. *Feed or nurse it at regular intervals*, not more than once in three hours after it is six weeks old. Don't feed it simply because it cries. Decrease the amount of milk on very hot days. Too much food and too frequent feeding are among the commonest causes of sickness.

3. *Bathe it daily:* The glands of the skin carry off nearly as much poisonous matter as the bowels. They both must be kept open in hot weather. Dry the skin well after bathing.

4. *Air it:* Out-of-door air is necessary. Keep the head shaded from the direct sunlight. In hot weather take the baby out early in the morning before 9 o'clock, when it is cool, and again late in the afternoon and *early* evening, but not late at night.

5. *Keep it cool:* If it is bundled up too much in summer it will become overheated. The more nearly naked it is, the better in extremely hot weather.

6. *Keep it in a quiet place:* A baby's nerves are very sensitive. Continued noise sometimes causes sickness.

7. *Give it water:* Between feedings give water freely, especially in hot weather. Use only water that has been boiled.

8. *Give no fruit* to a baby less than a year old. In summer give no fruit to a baby less than two years old. Fruit kills many babies.

9. *Give no solid food* to a baby less than one year old. For the first year of life the food should be *all milk*. For the second year, *chiefly milk*.

10. Call your own doctor, or if you have none, in summer notify at once the Department of Health if the baby has diarrhea, or is sick, and a doctor will be sent immediately.

11. *When the baby has diarrhea* stop all food and give only barley water until the doctor comes.

12. Use bottled or certified milk; Straus milk, or that prepared and furnished at the various dispensaries (not grocery milk), if you cannot nurse the baby.

**Medal for 20 Years' Hospital Service.**—John S. Langton, orderly and nurse at the Hudson Street Hospital, this city, received recently a gold medal from the Board of Governors and Surgeons of the New York Hospital, of which the Hudson Street Hospital is a branch, as a token of appreciation of twenty years' service.

**Work of the Lying-in Hospital.**—In the month of June the new lying-in hospital at Seventeenth street and Second avenue, this city, has had 434 applicants for treatment, of whom 119 were admitted and cared for in the hospital wards. The number of children born in the hospital during June was 90. For the same period in the outdoor department 266 have applied for assistance in their own homes, and 227 patients were treated in confinement. The number of medical visits made was 925.

**New Harlem Hospital.**—Dr. John W. Brannan, president of the board of trustees of Bellevue and allied hospitals, opened bids last week for the new Harlem Hospital in Lenox avenue, between One Hundred and Thirty-sixth and One Hundred and Thirty-seventh streets. The Board of Estimate appropriated $275,000 for the hospital building proper and $125,000 for the powerhouse and outlying buildings. The lowest bid for the erection of the hospital proper was $307,385, from James McFerran. The Board of Estimate will consider the bids and either reject them all on the ground that they are too high, or make the entire appropriation available for the hospital proper. The new hospital is to be of brick, trimmed with granite, with four-story wings and a five-story administration building.

**New Medical Directory.**—The Medical Directory of the City of New York for the current year has just been issued by the County Medical Society. It gives lists of all physicians in the States of New York, New Jersey, and Connecticut, lists of pharmacies, hospitals, benevolent societies, homes, asylums, and various other data of value.

**Statement by the Mayor of Ithaca.**—The mayor of Ithaca writes to the *Sun:* "Anent the report which appeared in your issue of Thursday, July 16, I would state for the information of the public: First, that the epidemic of last January was over months ago. Secondly, that the 'Ithaca Water Board' organized in April with authority to expend $750,000 for a supply of pure water, is sinking wells to veins at least 280 feet in depth, and more are projected. Thirdly, that wells now flowing aggregate 610,000 gallons per day; an amount which will be greatly increased when pumps are attached. Fourthly, that with a Board of Health of more than usual efficiency, composed of our best citizens, with artesian water largely used for drinking and cooking purposes, together with the fact that no expense has been spared to make this city the cleanest in the United States, gives me warrant for saying no city can be safer as a place of residence or to visit than is Ithaca at this time."

**Man Dies of Glanders.**—James M. Cahill, a fish dealer of Unionport, Westchester, died in the Presbyterian Hospital last Wednesday of glanders. The doctors at that institution say it is the first case that they have ever had.

**As to Insane Criminals.**—An important decision was handed down this week by Justice Lambert of the Supreme Court, Brooklyn, in relation to the incarceration of the criminally insane. The case was on the application of Alexander Gray for his discharge from the Matteawan Asylum. The writ to test the constitutionality of Section 454 of the Code of Civil Procedure, which provides that when the defendant charged with a crime is acquitted by a jury on the ground of insanity the trial court may, if it deem it best for public safety and peace, commit the acquitted defendant to the State asylum until he is discharged as cured. Gray was tried in the Court of General Sessions in New York County for assault in 1901, and acquitted by that jury on the ground of insanity, and the court sent him to Matteawan. Counsel for Gray claimed that the Court of General Sessions had no authority to pass upon the question of Gray's alleged insanity, and that exclusive jurisdiction in such cases is vested in the Supreme Court. Justice Lambert says: "The writ so far as is raised and presented the questions: First, that the Supreme Court has exclusive jurisdiction of insane criminals. The commitment is authority for the detention of the relator only during the period of his insanity. If he has recovered, he is entitled to a discharge."

## PHILADELPHIA.

**Health of the City.**—During the past week there was a decided falling off in the number of cases of contagious diseases. This was especially true of smallpox, there being but 24 new cases as compared with 54 for the previous week. On the other hand, there were more deaths of infants than during any

previous week of the summer. The deaths numbered 130, of which 109 were ascribed to cholera infantum and 21 to marasmus.

**New Hospital Dedicated at Chester.**—The J. Lewis Crozer Hospital at Chester was dedicated on July 17. This hospital is an H-shaped building, 161 feet in extreme length with two wings each 91 feet in length. It contains all the modern improvements of hospitals, including X-ray apparatus and well-equipped pathological and bacteriological laboratories. The surgical operating section is a suite of five rooms.

**Hospital Roof Garden Opened.**—The new roof garden for consumptives at the Philadelphia Hospital was formally opened on July 14 in presence of Mayor Weaver, Director Martin, and many members of the hospital staff. The roof garden is 200 feet long and 30 feet wide. Room will be furnished for from 80 to 100 cots.

**State Board of Health.**—The fifty-fifth meeting of the Pennsylvania State Board of Health was held at Marietta on July 16. Action was taken regarding the pollution of the Schuylkill and other rivers. Reports showed that during the months of May and June there were in the State 1,092 cases of smallpox, with 66 deaths. The Committee on Poisons and Explosives was instructed to prepare the draft of an act to prevent the use of toy pistols by minors. This action was taken because of the many fatal results from the use of those instruments on the Fourth of July.

**Gift for Philadelphia Medico-Chirurgical College.**—By the will of Spencer Morris, formerly professor of medical jurisprudence and toxicology at the Medico-Chirurgical College in Philadelphia, $12,250 is bequeathed to that institution, the income of which is to be awarded annually to the member of the graduating class who receives the highest general average at the final examination for the degree of Doctor of Medicine.

## CHICAGO.

**New Medical Dictionary.**—Dr. Karl von Klein, of this city, is compiling a medical dictionary which will include all medical terms in every language.

**Changes in Illinois Medical College.**—Dr. J. F. Presnell, late surgeon U. S. Volunteers, and Dr. Frank Byrnes, have been elected junior professors of surgery. Dr. Wm. F. Waugh has severed his connection with the college. The new buildings have been completed, one of which is devoted to anatomical laboratories, and the other is to be used as a training school for nurses.

## GENERAL.

**New Army Medical Journal.**—*The Journal of the Royal Army Medical Corps* is the name of a new journal, devoted to medical matters of interest to the British Army. The establishment of this journal has been in contemplation since 1864.

**Appointment of Dr. Eycleshymer.**—The University of St. Louis, which recently purchased the Marion Sims-Beaumont College of Medicine, has appointed Dr. Albert C. Eycleshymer, assistant professor of anatomy in the University of Chicago, as director of its Anatomical Department.

**Educational Bequests.**—The late Mrs. Harriet Lane Johnston, of Washington, has bequeathed $60,000 to the Johns Hopkins University for the establishment of three scholarships. She has also bequeathed $300,000 for the establishment of an Episcopal school at Washington for the maintenance, education and training of choir boys.

**Dr. Albert Appointed.**—Dr. Henry Albert has been elected assistant professor of pathology and bacteriology in the College of Medicine in the University of Iowa.

**"The Law and the Doctor."**—Amid the multiplicity of his daily duties, the physician has but scant time to cultivate more than a passing acquaintance with the collateral branches of his profession; the average practitioner, therefore, knows but little of the legal aspect of his relations to the body politic, or his rights and privileges, or his liabilities and responsibilities to his patients and the community at large. While pursuing "the even tenor" of his professional way, the doctor may suddenly be confronted with a summons and complaint in an action for malpractice, or may be called as an expert witness in a similar suit against a colleague. It is not the intention to urge the physician to become his own lawyer, but he should certainly acquaint himself with the fundamental principles of medical jurisprudence, so that he may be reasonably well prepared to defend his own or his brother physician's rights and privileges on the witness stand. With a view of placing such information at the immediate disposal of the doctor, the Arlington Chemical Co. has arranged to issue under the title "The Law and the Doctor," two 48-page booklets which shall present in condensed form and succinct style, an epitome of the essentially important features of (1) "The Civil Liability of the Physician for Malpractice" and (2) "The Physician as a Witness." These exceedingly practical monographs have been expressly prepared by an eminent member of the New York Bar, who is well recognized by the legal profession as an expert in this special branch of practice. The first of these reference text manuals is now ready for distribution, and after a reasonable interval will be followed by the second monograph. Copies may be had by applying to the above company.

**Yellow Fever Dies Out in Havana.**—Dr. Barnet, the Acting Chief of the Sanitary Department, announces that only three cases of yellow fever have entered Havana harbor this year. Of the three fever-stricken persons, all of whom came from Mexican ports, one died and another was discharged last week as cured. The remaining patient now here came to Havana from Progreso by representing himself as a passenger who had previously registered as an immune. The Government's surgeon at Progreso, Dr. Pla, has been recalled to Havana and probably will be dismissed for relying on a passenger's sworn statement without investigating.

**Sanitation in Manila.**—Surgeon-General O'Reilly has received an interesting report from the medical officers in the Philippines which shows a steady decrease in the death rate of the city of Manila as a result of the operations of the medical officers of the army. The death rate of Manila for the first quarter of the last four years has decreased steadily from 46.80 per thousand of the population for the first quarter of 1900 to 22.17 for the first quarter of 1903. Assistant Surgeon Munson says that the improvement in the conditions this year has been accomplished in spite of the fact that Asiatic cholera and bubonic plague had previously gained a foothold in the islands and that the existence of a largely unvaccinated population in the provinces meant a constant introduction into the city of the infection of smallpox. Cases of plague, cholera, and smallpox have occurred in Manila during the present year, but the precautions taken by the Board of Health have prevented an epidemic therefrom. "The sani-

tary results obtained in the last four years through American control have been accomplished," says Dr. Munson, "despite the naturally insalubrious location of Manila and its total lack of sanitation under the former sovereignty, which from the level site interfering with drainage, the many foul canals ramifying the city, the absence of any sewerage system, and the existence of an impure and insufficient water supply, and many old unhealthful habitations—have created sanitary problems of the greatest difficulty. The Board of Health therefore has been unable to turn previously existing methods and conditions to sanitary advantage, and has found it necessary not only to develop entirely new plans of improvement, but at the same time to combat the results of conditions inherited from the Spanish administration. The mixed character of the inhabitants with their prejudices, superstitions and largely primitive habits of life, also has been a constant obstacle in sanitary work."

**Autopsy of the Pope.**—Dr. Giuseppe Lapponi on July 22 presented to Cardinal Oreglia, Dean of the Sacred College, the official report of the autopsy performed yesterday on the body of Leo XIII. The report is chiefly important as disproving the presence of cancer or nephritis. The text of the report follows:

Yesterday evening, from 4 to 8, the embalming of the body of His Holiness, Leo XIII, took place. We began by injecting into the thigh over five litres of special preserving liquid. Having opened the abdomen, the lower viscera were extracted and were found to be perfectly healthy. The spleen and kidneys were also absolutely normal. In the latter the cortical substance was well preserved and of a pale pink color. After opening the thorax it was found that the heart, the aorta, and the carotid arteries were healthy except that in the arch of the aorta was found an atheromatous excrescence. Nothing unusual was found in the pericardium. The pleura on the left side was quite normal, but on the right side the pleura was full of liquid of an orange yellow color above and bloody at the bottom, with a large clot of fibrin floating. More fibrin was on the free surface of the pleura toward the ribs, with a slight scraping of fibrin easily detached, allowing a view of the serous surface. The upper part of the right lung was quite normal, but the lower part was somewhat hard and cracked at the touch, and while cutting a whitish, frothy liquid oozed out. The inferior lobe had partly adhered to the wall of the thorax, and when this was cut a dirty, white, abundant liquid, without gas, oozed out, showing complete hepatization. Afterward the thorax was filled with medicated cotton and an antiseptic absorbing substance, after which the incision made for the examination was sewn up and the body put in order.

**Obituary.**—Dr. Isaac N. Beegle died Monday in Ocean Grove, N. J., where he had practised as a physician since 1881. He was born in Bordentown, N. J., and was 56 years old.

---

**Vesical Infection with Coli Bacillus.**—An unusual complication following surgical intervention is reported by TOLÉDANO (Jour. de Méd. de Paris, June 14, 1903). Following a successful operation for recurring appendicitis, the patient developed, after forty-eight hours of satisfactory progress, fever, dyspnea and retention of urine, the specimen withdrawn by catheter being fetid and of abnormal appearance. Examination of the lungs revealed a congested condition of both organs and examination of the urine showed numerous bacteria, which proved to be coli.

# CORRESPONDENCE.

## OUR VIENNA LETTER.

(From Our Special Correspondent.)

VIENNA, Austria, July 11.

THE NEW VIENNA CHILDREN'S HOSPITAL.

UP to a short time ago Vienna was very insufficiently supplied with children's hospitals. In the year 1900 in all the children's hospitals of Vienna there were only 521 beds, so that, considering the number of Vienna's inhabitants, the proportion is one bed to every 3,107 inhabitants. In Budapest the proportion is 1 to 2,057. It is to be remarked that the better part of the existing hospitals are not at all up to the requirements of modern sanitary conditions, and they are situated at places where the surroundings are everything but favorable.

The new hospital is named the Kaiser Franz Josef Regierungs-Jubiläums-Kinderspital. The hospital owes its existence to the two million crowns fund of the City of Vienna, given in honor of the occasion of the 50-year jubilee of the Kaiser, and to the bequest of George Nellermann, consisting of 600,000 crowns. The government accepted this donation with the condition that it erect a hospital able to accommodate between 180 to 200 patients. The building was finished on August 18, 1902, the birthday of the Emperor Francis Joseph. The new hospital consists of three buildings of the already existing Wilhelminen Hospital, together with 34 pavilions, which can be grouped as follows: (a) Administration buildings; (b) Internal and Surgical Section, with 86 beds, in five buildings; (c) the infected section, with 106 beds, in 23 buildings.

One of the characteristics of the new hospital was to spare neither money nor land in order to apply the most modern achievements of medical science.

The buildings are of five kinds: those with 43, 17, 11, 5 and 2 beds; the latter are the so-called observatory wards for mixed infections or for patients whose diagnosis is not yet established. There are lofty, wide balconies built at the south side of the pavilions, whereon patients can lie in favorable weather.

In every pavilion, besides a tea kitchen, we find a lavatory, baths, closet, and also a complete laboratory, and a so-called prescription room, wherein more accurate examinations, minor operations, etc., can take place.

These pavilions are heated with steam and illuminated by gas and electric lights.

The cost of maintenance per patient is about $1.20.

The Internal Medicine section is under the supervision of Dr. Folsenek, that of surgery under Dr. Friedländer. The surgical compartment is connected with the operating theater through a roofed corridor. The orthopedic gymnasium is also connected with the surgical compartment, and is under the direct supervision of Dr. Lorenz. The nurses at this hospital either belong to or are under the jurisdiction of the sisterhood of the St. Vincent order.

The hospital is under the jurisdiction of a large and competent staff, with Surgeon-in-Chief Pospischil at its head.

# SOCIETY PROCEEDINGS.

## NORTH BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

*Stated Meeting, held April 13, 1903.*

The President, H. Brooker Mills, M.D., in the Chair.

SYMPOSIUM ON TYPHOID FEVER.

**The Diagnosis of Typhoid Fever With Some of the More Frequent Complications.**—This is the title of Dr. William Egbert Robertson's paper, in which he

called attention to the fact that there was no one symptom which could be relied upon for an absolute diagnosis in these cases, making it necessary to group together a number of symptoms upon which to base an opinion, the time and sequence of their appearance also being considered. Whenever possible, both clinical and laboratory observations should be employed. He believed that if the thermometer were more frequently used in office practice there would be fewer cases of the ambulatory type, as often a slight rise in temperature would put the physician upon his guard sufficiently to suggest rest in bed and other remedial measures at the time he is first consulted. A case was reported of a patient who had visited his physician, complaining of lassitude and inability to concentrate his mind upon his work, at intervals during three weeks, at the end of which time his temperature was taken, and found to be 103° F. He was immediately ordered to bed, but the case terminated fatally in a few days from hemorrhage of the bowels. The second case reported was that of a man who was admitted to the Episcopal Hospital, stating that he had not been well for a month, but continued to work the entire time. While at his bench, he was suddenly taken with cramp-like abdominal pain and immediately sent to the hospital where a diagnosis of perforation was made and an operation being performed was followed by recovery. Reference was made to the fact that, although we know the specific etiological factor that causes typhoid fever, diagnosis by this method is not always possible, even to the laboratory man, and the methods are not usually available to the general practitioner. The antecedent history of the patient, the mode of onset, temperature curve, relation of pulse and temperature, and the presence or absence of spots, are of material aid, but even considering all these symptoms a positive diagnosis is often impossible for several days. Frequently, however, the patient will complain of tiring readily for a few days prior to the attack, pains and aches throughout the body, loss of appetite, coated tongue, possibly slight looseness of the bowels, headache and epistaxis, and while a fictitious diagnostic value should not be placed upon these symptoms, their presence is sufficient in many cases to excite suspicion. The temperature was thought to be the most important early symptom and a careful record thereof during the entire course of the disease was recommended, semi-daily observations being made and recorded by some member of the family, if a trained nurse is not in attendance, careful observation usually revealing the fact that it rises from one to two degrees higher each day than the preceding. Another symptom that should always be considered is the pulse temperature ratio, as cases are frequently observed in which the temperature is as high as 103° F., while the pulse may not be more than 100 to 110, or, in rare instances, as low as 90 or less, and when repeated examinations show a daily increase in temperature without a corresponding increase in the pulse rate, especially when dicrotism is superadded, we have a most valuable symptom. While cases of meningitis often present similar conditions late in the course of the attack, the pulse becomes very rapid. This symptom is enlargement of the spleen which frequently can be discovered on palpation, as early as the end of the first week, and percussion over this region, as well as over the right iliac region will often elicit considerable tenderness. The next symptom is the appearance of the rose spots, which usually occur about the tenth day and last three or four days, upon which too much diagnostic importance should not be placed as they are absent in about 25 per cent. of the cases, and some other conditions present similar spots. Three classes of typical cases were mentioned as presenting more than usual difficulty: (1) The extremely mild cases, in which the duration of the attack is about as usual, but in which only moderate fever exists and the few symptoms arising are trifling in character. The second group are the abortive cases, which often begin rather abruptly and frequently with high fever and very pronounced symptoms for the first two or three weeks, and then go on to recovery. The third class are the ambulatory cases, which at first glance seem to belong to the first group, but were these cases diagnosed and put to bed early in the course of the attack probably fewer fatalities would occur. Rarely, according to Gerhard and Liebermeister especially, afebrile cases may be met with. The author stated that he had seen one which he had placed in that category. The patient had moderate fever, 100½° F., for forty-eight hours, after which it fell to normal and subnormal. Aside from temperature and temperature and pulse ratio these cases run a very benign course. Two types of the disease, both of which are abrupt in their onset, and of which very little mention is made in text-books, are the bilious and the respiratory, the former commences with bilious vomiting and the latter with bronchitis. While these cases are sometimes preceded by chills, they are not so much as formerly, when the antipyretics were more frequently administered for afebrile cases. Age, too, modifies the disease. The Widal reaction can rarely be obtained before the eighth day and, while of value in conjunction with other symptoms, it is not as important as the discoverer claimed. He then went on to say that complications were probably more numerous in this disease than in any other infection, and without mentioning them all he laid especial stress upon hemorrhage and peritonitis, preferring to use the term peritonitis, as other causes than perforation of the bowel not infrequently give rise to it. Speaking of hemorrhage, he said it occurred in about five per cent. of all cases and in from 10 to 20 per cent. of all fatal cases. It varies in amount from a mere trace to copious quantities, and from 1 to 15 or even 20 successive bleedings. A single copious hemorrhage may take place and death ensue, without any external exudence of bleeding. No clinical evidence of the smaller bleedings are elicited. Moderate hemorrhages are sometimes, seemingly at least, accompanied by more or less improvement; large hemorrhages always give rise to more or less collapse. In the great majority of cases pain immediately precedes the accident. Fall in temperature and increase in pulse-rate is also observed. Tenderness, localized or diffuse, more or less meteorism, and if the bleeding has been large, anemia, pinched features, cold extremities and sweating frequently supervene. Occasional rise of temperature, with or without the preceding chill may herald the hemorrhage.

**Perforation.**—Perforation occurs in about two per cent. of all cases, and from 20 per cent. to 30 per cent. of all fatal cases. Peritonitis, therefore, from all causes combined, is the cause of death in about one-third of all fatal cases. Recovery may ensue without operation, as clinical and post-mortem evidences demonstrate, but this seems to be rare, and surgical interference offers the only hope in the majority of cases and must be early to be of any use. Therefore, most minute and painstaking observation is necessary in every case of typhoid. Perforation is almost invariably preceded by bleeding for some hours, and immediately preceded by more or less pain, local or diffuse, and tenderness. Spasm and meteorism rapidly supervene. The absence of meteorism speaks for some other cause than perforation of the bowel; hence careful percussion, especially if the border of liver dulness is indicated. If one waits for indubitable signs of peritonitis, it is too late. Under cocaine an exploratory incision can be made with

impunity, and should never be omitted, where the case justifies the least suspicion. Clinical observation, he insisted, is probably of greater importance than laboratory aid in these cases; at least in the light of our present knowledge, but wherever possible, leucocyte counts, and, in cases of suspected hemorrhage, hemoglobin counts should be made.

**Mild Symptoms Masking Perforation With Peritonitis—Death.**—This was the title of a paper read by Dr. A. B. Hirsh, in which he directed attention to the large number of fatalities occurring in this class of cases, and felt that in view of the obscurity of the cases and the fact that celiotomy, when performed early, saves many patients, all cases of this character should be put on record. He then went on to report the case of a man, aged twenty-seven years, iron-riveter by occupation, of muscular physique, giving a negative family and personal history; he reported having had the appendix removed two years previously for a primary attack of appendicitis. Deafness consequent upon his employment, was added to the mental hebetude usually found in cases of typhoid and increased the difficulty of obtaining subjective symptoms. For two weeks prior to the time he came under observation, he had been suffering from increasing debility, fever, headache, some nose bleeding and nocturnal dreaming, but not vomiting or diarrhea. His temperature was 101.5° F., pulse 90, both of which continued practically unchanged throughout the progress of the disease; apathy was marked; the features were drawn and some emaciation was evident; a few rose spots were found; the abdomen was flat with absence of tympany, gurgling and localized or general tenderness; the liver and spleen were enlarged; constipation was present, necessitating the use of suppositories and enemata; the urine was normal, though diminished in quantity. The Widal reaction was positive. His progress during the first week proved uneventful. Icebag applications and alcohol rubbings were the only drugs administered for the fever, and trional or bromides for sleeplessness. On the seventh day there was a rise in the temperature to 103° F., but this was reduced by the application of the icebag and did not again return. On the morning of the tenth day tenderness in the left inguinal region was first noted, the area of gastric dulness was increasing, and this was followed by rapidly growing and general abdominal tympany; afterward the pulse became small, tense and wiry and very rapid and could scarcely be counted. Although the mental condition was unchanged, there was evidently failure of the vital powers, which forbade operative procedure, which was indicated by the undoubted peritonitis, and death ensued the next morning.

An autopsy upon the above described case was made six hours after death by Dr. H. C. Carpenter, who presented the following report: Body of white man, apparently about thirty years of age; extremely emaciated. Two scars are visible in the right inguinal region, each about two inches in length, one running along the outer edge of the right rectus muscle, with its center about McBurney's point; the other scar is over Poupart's ligament and running parallel with it. On making the incision the abdominal walls are very thin and when the peritoneum is opened a large quantity of gas with a decidedly offensive odor escaped. The pericardium contains slightly more fluid than normal. The heart is normal in size; the left ventricle is contracted; there are no clots, the valves are normal and the heart muscle is in good condition. The lungs are entirely negative; no stasis present. The kidneys are large; the capsule non-adherent and shows a moderate degree of parenchymatous nephritis. When the abdominal contents are exposed, an intense suppurative peritonitis is seen. The omentum covering the viscera extends down into the pelvic cavity where it is bound down by adhesions. That portion of the omentum which occupied the left side of the pelvis was gangrenous. The intestines were matted together with many pockets of pus lying between the coils. The pelvic cavity is full of liquid feces and pus. The last two feet of the ilium is covered with a fibrino-purulent deposit and is very dark in color. A perforation of the ilium is seen, about six inches from the iliocecal valve, the size of a pea, this is at the bottom of an ulcer three-quarters of an inch in diameter. The contents of the ilium are chocolate-covered liquid feces. Very few ulcers are present except in the last foot of the ilium; no ulcers are seen in the colon; the gall-bladder is distended with bile, but there are no gall-stones. The stump of the appendix which remains is not affected. The stomach is greatly distended and firmly adherent to the spleen and surrounding organs. The contents are a dark-brown liquid. No gastritis present. Spleen is moderately enlarged, soft and flabby.

**Treatment of Typhoid Fever Complicated With Indicanuria.**—This paper was read by Dr. Judson Daland, in which he stated that, while he formerly employed the Jaffey test for indican in the urine, he had lately modified his technic in accordance with an article published by Casimir Strzyzowoski, in the *Oesterreichische Chemiker-Zeitung*, for October 15, 1901, in which he gave the following method: "To 20 c.c. of urine of specific gravity of 1.015 (or greater) add 10 c.c. of a 10-per-cent. solution of neutral lead acetate. If specific gravity is less than 1.015, only take 5 c.c. of lead acetate solution and 5 c.c. of water. Filter through a dry filter and take 15 c.c. of a clear filtrate which corresponds to 10 c.c. of the original urine; add one drop of a one-per-cent potassium chlorate solution, then 5 c.c. of chloroform, and lastly 15 c.c. of pure fuming hydrochloric acid (specific gravity 1.19). Mix thoroughly by pouring repeatedly from one test tube into another. In ten minutes the maximum coloration has been reached, and the chloroform will be colored more or less blue according to the amount of indigo set free. Should the chloroform be colored violet by iodine add two drops of a five-per-cent. solution of thiosulphate."

This test, by the substitution of potassium chlorate, does away with the necessity for the chlorinated soda, which it was necessary should always be fresh. The author stated that the occurrence of indicanuria in typhoid was almost always to be found, although there are only certain cases where it is severe enough to demand especial attention. This condition, he stated, is to-day looked upon as being caused by materials putrefied in the intestinal tract; it is not claimed that it is a poisonous substance per se, but that through the absorption of it, other poisonous substances are formed, and we are, therefore, in the habit of looking upon indicanuria as demonstrating auto-intoxication of intestinal origin, and the conditions present in typhoid are those in which we would expect to find indicanuria present quite frequently. The treatment properly resolves itself into treatment for the auto-intoxication, which we are very well able to conduct during the first and second week of the disease, but from the third week until about the twenty-fifth day we are compelled to abandon purgative measures from the danger of perforation, and during which period the intestinal tract should be kept as much at rest as possible. It was stated that putrefying materials in the mouth, thus causing infection of the food, were believed to be a fertile source for this infection, and it was recommended that the mouth be kept in a thoroughly hygienic condition by frequently rinsing out, aided by the application of peroxide of hydrogen, if necessary, and

careful attention to diet. The use of fractional doses of calomel during the first two weeks of the disease, was recommended as an intestinal antiseptic, and it should be employed by placing the powder dry on the tongue, and allowing it to dissolve and slowly find its way into the intestinal tract. The calomel should always be given in combination with some inert substance, such as sugar or milk. The use of this remedy can also be resumed during the last week of the disease, when the danger of perforation is over. Beneficial results are also frequently obtained from the use of one dram of phosphate of sodium dissolved in a glass of hot water and given in the early morning. An occasional enema of normal salt solution at a temperature of 100° F. during the first two weeks of the disease may be valuable in relieving the constipation.

Dr. Anna E. Broomal showed the temperature chart of a case of typhoid fever of sixteen weeks' duration, with a temperature of 106° F. and a pulse of 180°.

Dr. Samuel Wolfe emphasized the value of the use of the thermometer in office practice and urged upon the members to adopt its use more generally, stating that he believed this would be the means of making much more accurate diagnoses. He felt that in the diagnosis of typhoid fever, the combined symptomatology should be considered, while the Widal reaction will undoubtedly occur in cases where the disease has been previously existent, a positive test will add weight to the other signs. Reference was made to the unusually large number of atypical cases which had occurred lately, and the value of a close study of indicanuria in this and other conditions commented upon.

Dr. Mordecai Price urged the use of calomel throughout the entire course of the disease, if indicated, and felt that the fear of perforation should not be allowed to preclude its employment. When there is a rapid pulse, normal or subnormal temperature, drawn facial expression and flabby peritoneum, perforation should be anticipated and operation done at once.

Dr. W. Duffield Robinson referred to a case in which the disease had lasted seventy-nine days with a continuous temperature; after the seventieth day he had begun the use of salol dissolved in white vaseline oil, the oil passed the bowel and was followed in nine days by a normal temperature. A case was reported of a dental student who had an attack of typhoid sometime before the Christmas holidays. On his return after the holidays he was taken with nausea and pain in the abdomen, which three hypodermic injections of morphine failed to relieve, and the next morning he was found to have a typical recurrent attack of typhoid. In the house where he had been taking his meals there were several other students (table boarders), all of whom took the disease, as well as the proprietor and his wife, the proprietor dying in six days after the onset of the condition.

Dr. Samuel P. Gerhard reported a case of typhoid fever complicated by colicystitis, which began in the usual way with headaches and high temperature, the latter symptoms being absent after the first week, at which time the delirium was very great. Calomel being given to relieve the constipation, salivation ensued, but during the fourth week she got up and stated that the abdominal tenderness had disappeared. Suddenly she complained of tenderness in the right side, stating that she felt as though she had eaten something that did not agree with her, based upon which supposition she was prescribed for. The speaker, being called to see her about midnight, found her suffering from intense pain in the right side extending over the back; and examination revealed a large lump on the right side, with perceptible swelling over the right chest. This subsided the next day and she appeared to improve for two or three days, when suddenly the pain returned and the swelling increased very much. Dr. George Ross was called in and obstruction of the bowels with possibly involvement of the gall-bladder suspected; there was no vomiting and the temperature was normal. After this condition had persisted for about a week she was removed to the hospital, and an operation revealed, upon lifting up the right lobe of the liver that the gall-bladder was gangrenous; and upon lifting up the left lobe about a quart of pus flowed out; the gall-bladder was suppurated and contained between 40 to 50 gall-stones. A drainage tube was inserted and the patient is progressing toward recovery, the bile flowing freely and the stools have resumed a normal color, showing that the cystic duct and the gall-duct are all right.

Dr. A. Bernheim recommended that the patient be kept as quiet as possible during the progress of the disease, and felt that it was especially derogatory to have a mirror in the room where the patient could see his own reflection, as it was apt to exaggerate the delirium. In reference to calomel, he stated that salivation had occurred much more frequently when he had used it in fractional doses than when he had employed it in larger quantities.

Dr. Wm. Egbert Robertson, in closing, felt that calomel could be used without detriment throughout the entire course of the disease, and referred to the reports of the Massachusetts Hospital collected by Dr. Fitts, which show that the mortality in this disease has not varied more than 1½ per cent. since 1836; being 11½ per cent. that year and last year it was 10 per cent., calomel being invariably used to the point of salivation in that institution.

Dr. A. Bern Hirsh, in closing, recommended prompt surgical interference in all cases of intestinal perforation and urged upon the members the necessity for careful observation in order to detect this condition. The value of dilute muriatic acid, especially in those cases where there is a furred tongue was commented upon.

Dr. Judson Daland, in closing, felt that the principal reason for the occurrence of salivation following the administration of fractional doses of calomel was the improper condition of the patient's gums, which should be carefully looked after. Muriatic acid was thought to be of value, and can safely be employed with the calomel, provided the two remedies are not given too close together.

*Stated Meeting, held May 12, 1903.*

The President, H. Brooker Mills, M.D., in the Chair.

SYMPOSIUM ON DYSMENORRHEA.

**The Etiology of Dysmenorrhea.**—Dr. J. Thompson Schell read this paper, in which he stated that the cause of the condition was a much discussed fact and is not established on any distinct scientific basis, dividing the causal factors into three groups: (1) local or pelvic, (2) general or constitutional, and (3) reflex. He stated that any diseased condition of the pelvic organs might be sufficient to cause dysmenorrhea, while on the other hand, apparently normal pelvic organs are found associated with severe dysmenorrhea, and it is not unusual to find all kinds of pelvic lesions, viz., antiflexions, various inflammatory conditions, etc., and no dysmenorrhea. He called attention to the fact that the old theory of mechanical obstruction to the flow is not so widely accepted as formerly, although antiflexion with much angulation is often associated with dysmenorrhea. The normal phenomenon of menstruation is strikingly similar to a pathological inflammation and nature makes provisions for the swelling incident to this phenomenon, but when there is any pathological condition present which would interfere in any way with the normal swelling, pain would naturally result. He believed that gout, rheumatism, anemia, general neurasthenia, etc.,

have all at times a causal relation to dysmenorrhea. The neurotic element is present in all cases, sometimes being the only cause and at all times having some influence on the production of the pain. The relationship between the nasal mucous membrane and the pelvis seems to be proven by the fact that applications of solutions of cocaine to the nose will in some cases relieve the dysmenorrhea and bring about a permanent cure.

**The Medical Treatment of Dysmenorrhea.**—This was the title of a paper read by Dr. Frank C. Hammond, of Philadelphia, in which he stated that in order to rationally treat a patient for dysmenorrhea the cause should first be ascertained; but there is a large class of cases in which the causative pathological conditions cannot be definitely determined. The treatment of dysmenorrhea may be divided into (1) the prevention of the attack, (2) the treatment of the attack, and (3) the treatment between attacks.

1. In cases depending alone upon congestion much good can be accomplished by free purgation the day of or the day previous to the flow. In girls in whom a demonstrable pathological condition cannot be ascertained, and in whom there is a normal anatomic relation of the pelvic organs, the tincture of gelsemium frequently affords the greatest relief; too much praise cannot be bestowed upon this drug when employed in this class of cases. It should be given ten drops three times a day, beginning a week previous to the beginning of the flow. Apiol, cimicifuga and permanganate of potassium are also useful.

2. All cases are benefited by rest during the period, in bed, if necessary; hot vaginal or rectal douches, and a hot water bag over the abdomen. When the pain is of a neuralgic character, antipyrin, gelsemium, cannibis indica, the bromides, caffeine, sodium benzoate, and viburnum prunifolium alone or in suitable combination are indicated. When congestive, with or without malposition of the uterus, free saline purgation, hot douches and hot sitz-baths. In addition to the drugs mentioned, the tincture of piscidia erythrina may be used with advantage, as may also the tincture hydrastis. The routine employment of opium was condemned and it should be employed only as a dernier resort. When the dysmenorrhea is due to vasomotor spasm, one one-hundredth of a grain of nitroglycerin, repeated in an hour, if necessary, will afford immediately relief. This drug is useless if employed otherwise than as herein indicated. The results of nasal therapy in dysmenorrhea, as reported by Flies, Ephraim, Linder and others are detailed.

3. The general health should be promoted by tonics, proper exercise, baths, suitably adjusted clothing, and attention to the bowels. Pelvic congestion should be depleted by local treatment, the use of the tampon, antiseptic and astringent applications, vaginal douching, high rectal injections, pelvic massage, local blood letting, atmocausis and the pessary. Intra-uterine applications are not to be recommended except for membranous dysmenorrhea. In all cases in which there is a demonstrable pelvic lesion, medical treatment is only palliative, surgical measures are necessary to effect a cure.

**The Surgical Treatment of Dysmenorrhea.**—This paper was read by Dr. William E. Parke, in which he divided the cases of dysmenorrhea into two classes: (1) Those curable by dilatation and curettage, and (2) those not amenable to surgical treatment. He divided the case of dysmenorrhea amenable to surgical treatment into (*a*) true obstructive dysmenorrhea; (*b*) membranous dysmenorrhea; (*c*) spasmodic dysmenorrhea; (*d*) congestive dysmenorrhea. The symptoms of true obstructive dysmenorrhea, he stated was a cramp like pain resembling those felt in labor, and may be caused by a new growth following operation, cancer, fibroid, or cicatricial tissue following operation; for the first two causes removal was recommended, while in cancer it is usually too far advanced to permit complete removal and we must usually be content with scraping out the canal. If the condition is due to cicatricial contraction following operation dilatation and curettage should be done, and the same is true if the pain is produced by antiflexion and angulation of the canal. Curettement should be done in all cases as the endometria are nearly always diseased. Membranous dysmenorrhea comes on at the beginning of the period and the pain increases in severity until the membrane is expelled, and wide dilatation, curettement and the application of carbolic acid were recommended. Spasmodic dysmenorrhea is characterized by severe cramp-like pains, usually of short duration, although they may continue sufficiently long to lose this distinction; they may extend over the whole pelvis and may or may not come and go with the menstrual flow. Many of these patients are sterile, recumbent posture gives but little relief, and some cases state that they are relieved themselves by alcohol. He believed that the operation of dilatation and curettage found its greatest field of usefulness in these cases, the reason for this being probably that the internal os in this condition is unusually sensitive and acts as a sphincter, and that forcible dilatation paralyzes the muscular fibers and relieves the spasm. In congestive dysmenorrhea, the pain precedes the flow by some days or a week, and may be simply an exaggeration of the aching that so commonly accompanies menstruation or it may be sufficiently severe to confine the patient to bed. The pain is situated in the pelvic area and does not give rise to the tossing about, fainting or vomiting, being often dependent upon changes in the uterus itself or its appendages, such as chronic metritis or endometritis, retroflexion, fibroid tumors and inflammation or prolapse of the tubes. When the condition is one of congestive dysmenorrhea pure and simple, surgical treatment is not indicated, but when it is secondary to the other conditions indicated, surgical treatment offers practically the only hope of relief. Dilatation and curettement, together with a removal of the appendages, if diseased, or in the case of a retroflexed uterus restoration to its normal position being the operations recommended. When fibroid tumors are the cause, their removal was advised, although dilatation and curettement will often give some relief. He called attention to the fact that there was frequently an association of one or more of the different conditions, and, therefore, care should be taken not to give too favorable a prognosis. He called attention to the fact that ectopic pregnancy was very often mistaken for dysmenorrhea and recommended thorough examination in all cases. If the appendages are diseased dilatation and curettement are contra-indicated unless the diseased appendages are removed simultaneously. He described the technic of the operation and laid especial stress upon the necessity for antiseptic technic in its performance.

Dr. F. Hurst Maier stated that in referring to the case books of the Jefferson and St. Joseph's hospitals, he found that the majority of the cases designated as "antiflexion with dysmenorrhea" occurred in married women and were sterile. He stated that in 135 of the cases the cause was designated as an inflammatory one, either of the uterus, the tubes or the ovarian structures, or in the form of a parametritis or cellulitis, being associated in a certain number of instances with a congenital antiflexion with an elongated cervix and shortened vaginal walls, but he believed that there was no doubt that, in certain classes of cases of dysmenorrhea, at least, the inflammatory condition was the cause of the pain. He believed that the old theory of mechanical obstruction

was entirely done away with and that when the pain is spasmodic we usually find it associated with some pathological condition. He felt that the majority of cases of vascular or nervous origin occurred in young unmarried women and better results would be obtained by vigorous general treatment to build up the nervous system, and their general condition, regulating the bowels, attention to the bladder, occupation, diet, rest and proper remedial agents during the menstrual period. In regard to surgical treatment, in those cases in which there is a distinct pathological lesion, such as fibroids, surgery must be resorted to; in cases of antiflexion of the uterus dilatation and curettage are the operations of choice; while in cases of hypertrophied elongated cervix, with shortening of the anterior vaginal wall, he recommended that the Dudley operation on both the anterior and posterior wall be used to supplement the dilatation and curettement.

Dr. A. B. Hirsh reported three case of pin-hole os cured by dilatation; all three having since married and two of them having borne children with no return of the dysmenorrhea. In each case the pain was absent until one week of the time of menstruation, increasing in severity during that time; in one case becoming so severe as to cause agonizing shrieks. Treatment was directed to the general condition in each case prior to the operation.

Dr. J. Thompson Schell reported a case of appendicular colic associated with dysmenorrhea, in which the dysmenorrhea was cured by the removal of the appendix. While he believed a dilatation of the cervix was of value he felt that we should not be too sanguine of a cure in these cases of pin-hole os, by means of this treatment.

Dr. Frank C. Hammond, in closing the discussion, remarked that he had found hot vaginal douches of value in these cases. He believed that whisky should be employed with caution, owing to the liability of the alcoholic habit being formed. In regard to membranous dysmenorrhea, he believed that pregnancy was as near a cure as could be established, but that it was very difficult for pregnancy to exist under these circumstances.

Dr. William E. Parke, in closing, referred to a number of cases of membranous dysmenorrhea which had come under his observation at the Kensington Hospital, some of which had been cured by the treatment outlined in his paper. While these cases may be relieved for several months, he expressed the opinion that they were rarely permanently cured.

Dr. Anna M. Reynolds reported a case of a monstrosity occurring during a twin pregnancy, exhibiting the specimen.

Dr. E. Franklin Smith, of New York, reported a case which had come under his observation a few years ago, in which the abdominal wall of the child ruptured during delivery; the child was perfectly formed, except the anterior abdominal parietes, which was almost as thin as an egg's membrane, every vestige of muscular fiber from the pubes to the ensiform cartilage and from the median line to the spinal column being missing.

---

## HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

*Regular Monthly Meeting, held April 25, 1903.*

The President, Frank H. Daniels, M.D., in the Chair.

**Fusiform Dilatation of the Esophagus Simulating a Diverticulum, with Report of a Case.**—This is the title of the paper of the evening, which was read by Dr. William B. Coley, in which operation was followed by a fatal termination.

**Obstruction of Esophagus.**—The patient was complaining of considerable difficulty in swallowing, so that he had been unable to take food or drink for some time, the condition being complicated by a swelling in the thyroid region and the return of swallowed material unaltered, so that it was evident it had not been in the stomach. The most interesting feature of the case was the occurrence, after the taking of a second glass of liquid, of a growing prominence in the anterior cervical region that made the thyroid project very noticeable. Such swellings have been noted in connection with diverticulum of the esophagus, which occurs by preference in this region, as Dr. Coley showed by the illustration from Nothnagel's monograph on obstruction of the esophagus in his encyclopedia of pathology and therapy.

**Family and Personal History.**—The patient was about forty-five years of age, was born in the United States and says that his mother died with cancer of the uterus. His own first symptoms consisted in inability to swallow meat and bread, the material getting stuck, as he said, in the lower part of the neck. Since that time he has had to be careful to use practically nothing but liquid food. Three years ago he began to notice that a swelling occurred here whenever he swallowed. Usually when the material swallowed was soft he succeeded in getting it down. For the last three months, however, even liquid food has often refused to pass, and, as a result he was losing weight very rapidly. For the last ten days he has been able to take only one soft-boiled egg. Inspection and palpation show a distinct swelling at the right of the thyroid and while the act of swallowing seems easy, this swelling occurs after a glass and a half has been taken and few minutes later the whole quantity is regurgitated evidently without any of it having reached the stomach. The passage of a stomach tube shows that an obstruction exists about 7½ inches from the teeth. After considerable manipulation, however, the tube could be passed on into the stomach. Because of this it was resolved to feed the patient, in order to make his condition better for operation. The food was given by the stomach tube but the patient did not gain very much in weight. It seemed evident that a diverticulum of the esophagus existed at the usual location for such a pathological condition. As is well known this condition is apt to occur in the neighborhood of the cricoid cartilage and it is said to be due to the pressure of precocious bony degeneration of the cricoid ring, producing thinning of the esophageal wall. As the patient was growing weaker in spite of the tubal feeling, operation was decided on after four days, in the hope that the pouch might be removed and the entrance to it closed up so as to give ease in swallowing once more.

**Fatal Termination—Autopsy.**—The dilatation of the esophagus was found to extend very deeply down to the thorax. It was fusiform in character, involving the whole diameter of the esophagus and nothing could be done to relieve it. The patient died on the second day after the operation from congestion of the lungs, which had not gone on to the pneumonic stage. The congestion was thought to be due, to some extent at least, to absorption of thyroid substance, since the most prominent pathological condition found in the thyroid gland, when that gland was exposed, was a large tumor of the right lobe of the thyroid extending down below the sternum and evidently bearing a distinct etiological relation to the obstruction of the esophagus, since its presence must have caused pressure upon the important nerves in this region. The tumor was found to be largely cartilaginous in composition and was very difficult of removal because of the free bleeding from enlarged veins which ensued when its substance was incised. This tumor was evidently of slow growth and, though non-malignant in character, was of the kind that might readily take on malignancy. It had apparently

been growing since the first manifestation of symptoms in the case and the fact that portions of it, were below the sternum made the pressure symptoms produced by it much more serious than would have been the case if the enlargement had occurred in the neck above the sternum.

**Autopsy Findings.**—At the autopsy it was noted that no septic condition was present and the esophagus itself had been very little interfered with. The autopsy showed besides a constriction of the esophagus at the point where the difficulty of swallowing occurred and then a spindle-shaped dilatation of the esophagus reaching down to the cardiac end of the stomach. This dilatation of the esophagus was thought to be due to the pressure of the tumor of the thyroid previously described.

**Diverticula of the Esophagus.**—Modern methods of diagnosis are making it clear that this condition is much more common than has been thought. In 1880 there were only 18 cases in the literature. In 1890 some seventy cases could be collected. Some of the fusiform dilatations of the esophagus reported have been very pronounced. Rokitansky described a case in which the esophagus was as large as the arm of a patient. The common symptom of these cases is the feeling of the patient that food never reaches their stomach. At times, besides the dilatation of the esophagus, there is a lengthening of it, which causes it to assume something of a serpentine form. Dilatations are usually due to spasm of the cardiac orifice with secondary relaxation of the muscle above. Sometimes these dilatations occur as the result of even functional or so-called hysterical spasm of the esophagus. The mechanism of their production in these cases is not easy to understand.

**Incidence of Diverticula.**—Diverticula of the esophagus are likely to occur in either sex and have been reported at all ages from twenty to extreme old age, though the symptoms are commonest in the two decades between twenty and forty. The prognosis of the condition is very unfavorable, since, after a time, most of the food finds its way into the diverticulum and is vomited thence without serving in any way for the nutrition of the patient. Death from inanition is almost the rule in unoperated cases and is apt to be slow and painful. Operation is not as unfavorable as might be expected and in recent years the proportion of recoveries has been constantly growing in the hands of good surgeons. Operation should be suggested, however, before the patient has become exhausted by the condition.

**Radical Operation.**—Dr. Maurice H. Richardson, of Boston, has recently reported some cases in which he has succeeded in extirpating the diverticulum closing the opening into the esophagus and bringing about a complete cure of the pathological condition. In the literature there are some 56 cases reported, 17 of which have been operated upon with only one death. Diverticula are often spoken of as pressure diverticula, especially when they occur in the upper part of the esophagus and it is a very curious observation that in most of the cases no stricture is found to account for the beginning of the diverticula pouch. It is not always easy to decide what is the source of the pressure that leads to the weakening of the esophageal walls. In the present case the fusiform dilatation of the esophagus was evidently due to the pressure of the thyroid tumor.

**Similar Case.**—Dr. Palmer Cole said that he had recently had experience with a case having many of the features of the case described by Dr. Coley. The patient is a young man of twenty who came to Dr. Cole's office in a state of extreme distress with a very anxious face, blue hands and lips and clammy coldness of the extremities and complained that he was choking. He had the feeling of a lump in his throat which made it impossible for him to swallow and he frequently put his finger to his collar, as if to relieve some constriction. He had taken no solid food for two years. On the morning before his visit to Dr. Cole's office he had swallowed some dry cracker, but had not succeeded in getting it down. To this he attributed his exhausted condition. Dr. Cole exerted a gentle pressure upon the tumor present in the cervical region and after a time massage seemed to give some relief. The patient was given ten grains of carbonate of ammonium as a temporary stimulant and this seemed to get to the stomach without difficulty. In order to carry out the massage Dr. Cole had to get his fingers deep down under the sternum and this seemed to relieve the condition as if something had been dislodged.

Dr. H. S. Spooner, in discussing the case, said that just above the spasm of the esophagus hypertrophy of the muscular walls occurs and this is apt to be followed by dilatation. If the dilatation occurs more in one part than in another, that is, if there is a localized weakening of the muscles, a diverticulum results. If not, then a more or less regular dilatation occurs.

**Difficulty of Diagnosis.**—Dr. Walsh said that he had seen a case of functional stricture of the esophagus in Professor Nothnagel's clinic, which illustrated very well the difficulty of diagnosis in these cases. For several years a young man had had a series of attacks of difficulty of swallowing. For days at a time he would not be able to get anything into his stomach, even with the greatest effort. Usually after the passage of a sound he secured control over his swallowing mechanism, until some emotional strain or overwork or worry made him liable to have this spasmodic constriction of the esophagus once more. Professor Nothnagel was of the opinion that the recurrence of these spasmodic constrictions might ultimately lead to the production of a diverticulum of the esophagus. There seemed to be absolutely no reason for the recurring spasm, except the intensely neurotic condition of the patient, who had a family history with nervous tendencies on both sides. Dr. Walsh said that on the other hand the recognition of malignant stricture was not always easy since it ran a more or less latent course until serious narrowing of the lumen of the esophagus had been brought about. In some patients very little complaint was made until actual impossibility of swallowing solid food developed. In a case seen in Vienna the man had found difficulty in swallowing solid food only for a few days when somebody suggested that such difficulties of swallowing might be overcome by taking a quantity of pepper seeds in a glass of beer. This was followed by complete inability to swallow anything, even liquid, and the sounds could not find any passage into the stomach. At the autopsy it was found that the pepper seeds, about the size of peas, had lodged in a tortuous canal which represented the lumen of the esophagus through a rather long malignant growth of that organ. Their presence had given rise to some edema which absolutely closed esophageal opening and made even the passage of liquid impossible. The case illustrates the possibility of latency in malignant cases until serious conditions may follow attempts at swallowing solid food and when the diagnosis from the suddenness of the attack and the absence of previous history may lead to a suspicion of the functional character of the affection.

Dr. Coley in closing the discussion, said that in these cases it is often a mystery how the stomach tube passes, yet, after the swallowing of even a few drops of liquid, reflex spasm occurs with complete closure of the esophagus. It is curious that sufficient hypertrophy of the muscles of the esophagus above a functional constriction does not occur to enable the esophagus to pass on the food in spite of the resistance. Curiously, however,

little hypertrophy of the esophageal muscles is found at the autopsy of these cases, as a rule.

**Hodgkin's Disease Relieved by X-rays.**—Dr. Coley reported a case of advanced Hodgkin's disease, in which a great improvement of symptoms with reduction in the size of glandular swelling occurred as a consequence of repeated exposure to the X-rays. The patient was a man of forty-five years who noticed four months ago that the glands on the side of his neck were becoming enlarged. After these his axillary glands then his inguinal glands became involved. Then he lost considerably in weight. His spleen reached within a couple of inches of the opposite anterior superior spine and in its lowest portion was down almost to the pubis. The blood count showed the presence of 70,000 leucocytes with a number of red cells distinctly below normal. The X-rays were employed as a last resort, though without much hope. Exposures were made of the enlarged glands in the neck and axilla for some ten minutes at a time, four times a week. He began to improve at once. Within two weeks the spleen was distinctly smaller, the glandular swellings had gone down on the sides and the number of leucocytes was markedly reduced. After six weeks of treatment the leucocytes came down to 12,000 and the spleen was reduced to less than one-fourth its original size. Now practically all the glandular enlargements are gone and the man has gone back to his work. He considers himself entirely cured.

**Ultimate Prognosis.**—The ultimate prognosis in cases that are relieved by exposure to the X-rays is not as good as might be anticipated from the prompt improvement which takes place and the amelioration of the general condition which follows. Dr. Williams, of Boston, who has large experience in X-ray work, reports some cases of Hodgkin's disease in which prompt improvement took place, yet the affection recurred and ultimately with fatal termination. Dr. Senn, of Chicago, reports two cases entirely cured by the X-rays, but the time since the relief of symptoms is not long enough to be definitely assured against return. Dr. Senn inclines to the opinion that Hodgkin's disease is due to an acute infection. There are some who consider that the enlarged glands are really the result of a generalized glandular tuberculosis. Tuberculous inoculations were made into guinea-pigs, but the animals disappeared just about the time autopsies were to be made—stolen from the laboratory, it would appear—and so the result was not known.

**Continuous Ether Apparatus.**—Dr. H. S. Spooner described an apparatus for the giving of ether continuously during mouth operations in such a way as to avoid interference with the operator by the presence of a cone or other large inhaling apparatus. The tube through which the ether is given is fastened in the angle of the mouth and the ether flow is regulated by means of valves. No special irritation of the mucous membrane takes place and the operative work may be continued without any attention to the anesthesia, which can be made as deep and long-continued as is necessary.

**Spindle-cell Sarcoma and X-rays.**—Dr. Coley described a case of a woman, who came from Boston in the spring of 1901, suffering with a large tumor in the right iliac fossa. This was entirely too large to permit any hope of radical removal and extended up as high as the umbilicus. It had been growing larger and harder for some time when the patient came to be treated by the mixed toxins of erysipelas and the *Bacillus prodigiosus* with the hope of possible relief. Under the repeated injection of the toxins the tumor began to decrease in size, but after some time the decrease stopped and it remained at a standstill. Even this was a distinct improvement over the condition of rapid growth that had been the rule before. After a time, however, the toxins evidently lost their influence and the tumor began to increase in size again. The abdomen became as large as that of a woman in the eighth month of pregnancy and the general health became very unsatisfactory. The case seemed utterly hopeless and the patient herself had given up all prospects of relief.

**Immediate Improvement Under X-rays.**—As a last resort the X-rays were tried and, after a time, improvement began once more. There were periods of fever evidently due to the absorption of septic material from the broken-down tumor which was disintegrating under the influence of the X-rays. After three months of treatment she was so much improved that she began her occupation of teacher once more in the fall, and went to Boston only on Friday, Saturday and Sunday for treatment. She has now become practically well and the tumor has entirely disappeared. She is an intelligent person and describes very clearly just how the series of changes took place which brought about the disappearance of the tumor. After exposure to the X-rays she would note a spot of the tumor sorer and tenderer than the rest and then it would become distinctly less hard. After a time a hollow would form at this point, showing that there had been absorption of material and this hollow would increase in size by absorption from its edges. During this process of absorption fever always occurred, but this subsided of itself after a time.

## THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, held at the New York Academy of Medicine, May 11, 1903.*

The Vice-President, Ransford E. Van Gieson, M.D., in the Chair.

**Experimental Researches on Resuscitation After Death from Chloroform.**—This was the title of a paper by Drs. Robert Coleman Kemp and A. W. Gardner, which was read by Dr. Kemp. In addition to reporting a series of experiments conducted by the authors, it was proposed to describe a simpler and what was believed to be a safer method of massage of the heart than that which was first credited to Prus, and to call attention to certain facts in attempted resuscitation from anesthetics, drowning and allied conditions, which might possibly be of practical benefit. The general method of preparing the animal to be experimented upon was described, after which it was stated that in some cases respiratory tracings were taken by means of a compression bulb held in position by a band strapped about the chest. No further respiratory tracings were taken after the operation of opening the chest was begun. In some of the animals only cardiac tracings were taken but careful note was made above these the instant respiration ceased. In others no tracings were taken, but the following important facts were noted: The time of cessation of heart and respiration; the period when the partial movements of the heart ceased, after the thorax was opened; the length of time thereafter that massage of the heart was begun; the time the heart began to beat alone.

In some cases, when the heart seemed flabby and empty and did not react to massage, a small infusion of normal saline solution at 120° F. was given, as an additional stimulant, and also to furnish fluid to work upon. When the heart seemed dilated and full of blood, this was unnecessary. After resuscitation such an infusion, given before removing the animal from the Nélaton to the dorsal position, in order to prevent shock, was found extremely efficacious. Artificial respiration was continued until the wound in the chest

was closed for the purpose of preventing collapse of the lung. In all cases, after the chest was opened, the heart was allowed to come to an *absolute standstill*, without the slightest movement of any description, even partial, being perceptible from sight, feeling or compression. A period of three, five, ten, and, in one case, nearly sixteen minutes was allowed to elapse before massage of the heart was begun. (The tracings were demonstrated, and accurate figures given.) As to the mode of death from chloroform inhalation, in most of the cases respiratory failure occurred first, followed by heart failure. In several instances, however, heart and respiration failed synchronously. In one case the heart failed as if it had been pierced.

**The Limitations of the Usual Methods of Resuscitation Demonstrated by the Kemp-Gardner Experiments.**—A careful study of these demonstrated the following facts: The chloroform was pushed to the point of complete respiratory and cardiac failure. The heart-beat could not be detected, the pulse could not be felt, nor could pulsation be obtained in the carotid and femoral arteries, which were previously dissected out, the one for attachment of the manometer, the other for infusion into the vein. The animal, clinically, is apparently dead; yet even at this stage the manometer tracings demonstrate an occasionally and scarcely appreciable cardiac beat. Physiologically, death has not occurred; and, in fact, not clinically, for even in this extreme condition the animal can still be resuscitated by the usual methods—infusion with hot normal saline solution, inversion, artificial respiration, hypodermics, etc. If, however, no effort at resuscitation is made, the manometer tracings finally cease absolutely, and the animal, according to the physiologist, is at last dead. If the thoracic cavity be now opened and the heart carefully examined, it will be noted that though the organ in its entirety has absolutely ceased to beat, yet for a time (several minutes in many instances) there is a partial muscular contraction occurring occasionally in one or both ventricles, which, however, is so slight and incomplete as to produce no trace by the manometer. Even at this stage the usual methods of resuscitation will restore the animal in some cases. Finally, and in the last stage, the heart becomes absolutely motionless and inert, to sight, touch and compression. Though the vital spark exists, as may be demonstrated by the radical method of restoration, yet the animal may be considered as *dead*, since the usual methods of resuscitation at this point absolutely fail. Some *vis a tergo* agency is positively essential to start up the heart action, and it is, moreover, necessary that this should be quite vigorously applied. It is this indication that cardiac massage, and that alone, fulfils, for it must be remembered that there results from its employment not simply the interesting experiment of the return of heart-beat for a period of time, but an actual restoration of all the bodily and mental functions.

**Results of Cardiac Massage.**—From the standpoint of the clinician, the authors believe that in certain cases cardiac massage is of practical utility, and that, so far, it can be replaced by no known method. They succeeded in resuscitating 11 out of 23 animals (dogs) after absolute cessation of heart-action to sight, touch and compression of the organ, and that, too, after it had remained in this condition for variable periods without any efforts at resuscitation. In nine of the animals the functions of intelligence, drinking, urination, defecation, etc., were restored to normal. In many of the animals under experimentation, artificial respiration, inversion, infusion with hot normal saline solution, etc., were tried, with resulting failure until cardiac massage was added to the treatment.

**Methods of Massage.**—The method usually advocated consists in the resection of several ribs, the insertion of the hand into the left pleural cavity, and rapid manual compression of the heart. In the experiments several methods were tried, including the above. Some successful cases were secured by each, but one of these was found to be far safer and more rational than the others. This was described as follows: The animal is placed in Nélaton's position, which throws the heart forward against the chest and somewhat upward. An incision is made over or slightly below the apex, and, if necessary to secure more space, a small piece of the fifth and sixth ribs may be resected. The index and middle fingers are passed over the margin of the heart and behind it, near the apex, and pressure is made on the heart against the chest. Or, the opening being enlarged, the fingers may be placed behind, and the thumb between the apex and chest-wall, and the heart is then rapidly squeezed between them. It was found that a rapid intermittent (double action) pressure was the most successful in causing resuscitation, and this, in effect, imitates the dicrotism of the pulse, as is shown in the tracings. A rapid single action pressure was not so efficacious. In the operation upon the thorax it was found to be the best method to make an oval skin-flap, and, reflecting this forward, to open the thorax about the middle of the base of the flap. In some cases, during the compression of the heart, a small amount of hot normal saline solution (at 120° F.) was poured on the heart, through the thoracic wound, in order to prevent chilling of the organ. It is also well to wrap the animal in hot towels for the same reason.

After the heart has begun to beat alone the chest wound is rapidly sutured. As it was found that the manipulation in the chest might have a tendency to cause exudation, in most cases a strand of sterile gauze was inserted through a small counter-opening, for drainage, at the base of the flap. In order to keep the lungs well filled with air, artificial respiration was invariably kept up until the thoracic wound was closed. Before removing the animal from the Nélaton position an infusion of normal solution (4 to 6 fluid ounces at 120° F.) was given, to prevent shock. The manometer was then disconnected, the carotid artery and femoral vein tied off, and the external wounds sutured. The animal was removed to a box, wrapped in cloths, and given a hypodermic of morphine to quiet him. The dogs lived from two to twenty-four hours, and most of them became active and hard to control. The autopsies demonstrated in some cases that they had torn out sutures, with resulting pulmonary collapse and secondary hemorrhage. Some cases were infected through their own efforts, and some undoubtedly through the operators' hurried and insufficient attention to absolute antiseptic details. None of the cases in which the last method was employed showed any damage to the heart or pericardium. With a more perfect technic there seemed to be no reason why death should occur at all.

**Hoyt's Pump for Artificial Respiration.**—This instrument was devised for the authors by Mr. J. T. Hoyt, electrical expert to the physiological laboratory of the Medical Department of Columbia University. It is furnished with entrance and exit valves at the base, and by means of a V-attachment, oxygen and air can be administered in combination. It can be clamped to a table, and is readily taken apart. An improvised filter for the air can be attached, or a simple method devised to carry the air through gauze impregnated with an anesthetic, so that an operation on the lung can be carried on and collapse of the organ prevented. Each full stroke of the piston represents 22 cubic inches

of air, the normal inspiration being about 20 cubic inches in the adult. By means of a small governing-rod to regulate the height of the stroke (markings being placed on the rod), the piston-stroke can be made to correspond with the amount of air required to inflate the infant or child. This portable pump was believed to be extremely useful in resuscitation in cases of collapse on the operating table, in drowning, in gas or opium poisoning, and in respiratory failure in the newborn. (Dr. Kemp demonstrated the use of the pump on the body of a large dog.)

**The Kemp-Gardner Intubation Tube for Artificial Respiration.**—This has proved eminently successful for intubation of animals. It is practically an O'Dwyer tube with a hollow handle. The part entering the larynx, however, is somewhat shorter, while the distance between the bulbous enlargement which rests on the vocal cords and the curvature at the base of the tongue is slightly longer, to allow for the extended position of the head when the patient is inverted. There is a small opening in the upper surface of the tube which, by means of the thumb, can be regulated as an expiration valve. This tube is believed to be much less liable to damage the soft parts (larynx and cords) than the Fell-O'Dwyer tube. The authors consider that intubation of the larynx is the only accurate method to secure perfectly satisfactory artificial respiration. There can be no question that in a large percentage of cases artificial respiration is improperly performed.

**Infusion.**—Heat, as a cardiac stimulant, is one of the most important factors, and the temperature of normal saline solution, as Dawbarn has demonstrated, should be 120° F. This solution actually reaches the heart at about 110° F. If a higher temperature is employed (125° to 130° F.), some crenation of the red blood corpuscles occurs. When there are commencing signs of shock, a preventive infusion should be given. If this fails, a slow infusion of 1½ liters, continuously trickling into the vessel at a temperature of 120° F. for forty-five minutes, may be efficacious.

**Complete Inversion of the Patient; Nelaton's Position.**—The importance of complete inversion cannot be overestimated. The semi-oblique or oblique position is not sufficient. Dawbarn advises hooking the legs at the knee-joint over the edge of the table, and this might be employed with advantage in drowning cases, artificial respiration being performed while the patient is inverted. This would seem to be more efficient in clearing the chest and larynx than by the present methods in the practically dorsal position, and is undoubtedly more serviceable in stimulating the heart. In one of the experiments severe pulmonary edema was caused by too rapid infusion. By complete inversion of the dog, accompanied by artificial respiration, it was possible to pump out the lungs, the fluid flowing copiously from the animal's mouth.

**Cardiac Massage Performed in the Human Subject.**—In the summer of 1901, Dr. Kemp made use of this procedure in the case of a young girl who died suddenly from shock after a simple operation for opening an accumulation of pus in the left side of the abdomen, in which nitrous oxide gas was the anesthetic employed. The father gave permission to try massage of the heart, and the method described was adopted, but without success. The case was in every respect a most unfavorable one, as the patient was pyemic, and, in addition, weakened by several previous operations. In conclusion, the conviction was expressed that massage of the heart was both sound therapeutics and a perfectly justifiable measure in all cases of death from chloroform or any other anesthetic, as well as from drowning and allied conditions, when all other means of resuscitation have failed.

**Simply an Arrest of Function.**—Dr. William H. Thomson thought the importance of this matter could hardly be overestimated. In the experiments described by Dr. Kemp it would be difficult to call in question the main facts of the condition; for all intents and purposes the dogs were actually dead. But although they were dead, the mechanism of life was still intact. It was a characteristic of deaths from drowning and anesthetics that the mechanism was not all affected; there was simply an arrest of function, and therefore for a time there was a possibility of resuscitating the patient. It had occurred to him, however, as to the application of these experimental researches, that possibly what might be true for even the higher animals might not be true for man. The human heart, it was well known, was much more subject to shock. Still, he spoke only on a priori grounds, and the practical utility of the procedure described in the paper could be determined alone by actual experience.

**Might Not Time be Saved by Approaching the Heart from the Abdomen?**—Dr. R. T. Morris said it had occurred to him that perhaps a little time might be saved if the heart were approached from the abdominal cavity. In that case no time would be lost in resecting the ribs, and moreover many of the instances in which cardiac massage might be called for occurred during operations in the abdomen when that cavity was already opened.

**Let the Lungs Collapse.**—As to the maintenance of artificial respiration, while the chest was being opened, in order to keep the lungs filled with air, he thought it was a question whether this was not a mistake. Collapse of the lung was only a trifling matter. The artificial production of this condition was an excellent resource for the arrest of hemoptysis. He would, therefore, suggest that the lungs should be allowed to collapse until the operation was concluded. There would be no difficulty in getting them back to their normal condition afterward. In lung surgery one great trouble often was to keep the lungs collapsed, and nitrogen was almost the only thing that would do this.

**Whisky and Morphine Before the Use of Anesthetics.**—Dr. R. H. M. Dawbarn said it seemed not creditable to the profession that such wide differences of opinion should still exist as to certain points regarding both prevention and treatment. As to the former, with hardly any exceptions in twenty-two years' experience he had used a very small dose of morphine, guarded by atrophine, subcutaneously, and a large dose of whisky by the mouth, an hour before operating, and had never yet had cause to doubt its wisdom for several reasons. This was the rule also, he thought, among surgeons in this city.

**Alcohol Unjustifiable in the Treatment of Anesthesia Narcosis.**—As to the treatment, we see to this day a patient, with death already impending, commonly receiving alcohol in large amounts by the needle, a practice radically different from its use in *prevention*. According to Prof. N. C. Wood, this is little better than murder, for we are then treating by a narcotic drug a patient already too deeply narcotized.

**Means of Resuscitation.**—To speak of ways of undoubted value, whether the respiratory center or the heart be at fault, Dr. Dawbarn said he would advise a prompt inversion by aid of the knees hooked over the table, artificial respiration by the rapidly repeated compression of the chest wall, and very hot salt water (120 to 125° F.) poured freely into the rectum. Nélaton's position is of the utmost value in stimulating the heart by distending the right chambers by weight of blood. Of course, not a drop of blood between the feet and heart can reach the brain except by being pumped through the heart. As to the proper degree of heat,

whether by rectum or intravenous introduction, he worked this out in the Columbia Physiological Laboratory in 1890 to 1891 by aid of the kymograph and manometer, and Dr. Kemp has verified his results, then published. Although it must be seldom indeed that such a measure as cardiac massage will be needed, we owe Dr. Kemp much appreciation for putting this measure upon much firmer and more scientific grounds than was ever before the case. After the demonstration which had been given this evening, he thought no surgeon could be said to have done his whole duty in a case of anesthesia narcosis, where other means have failed, until he had resorted to massage of the heart. As to Dr. Morris's suggestion to open the abdominal cavity in order to save the time consumed in cutting away the ribs, there was no necessity whatever for such a resection, as the operation could be satisfactorily performed without this.

**Opening the Chest for Hemoptysis.**—As to opening the chest for the treatment of hemoptysis, he would consider such a procedure reckless in the extreme.

**The Treatment of Chloroform Syncope.**—Dr. Thomas L. Bennett said that in chloroform syncope the main dependence must be placed on mechanical means. Personally he had been invariably successful with the method advocated by Maas, which consists of the application of forcible compression of the chest over the heart sufficient to create an artificial carotid pulse, the compressions being made at the rate of 120 per minute. Inversion he believed to be unphilosophical and fraught with danger. As to the hypodermatic injection of drugs, this was practically useless in such an emergency, as they could not be absorbed until the crisis was passed and the patient on the road to recovery. In any case, where all other means had failed, he would not hesitate to resort to cardiac massage, and he believed that this procedure would prove of great value.

**The Routine Use of Morphine and Whisky to be Condemned.**—As to the routine use of morphine before giving an anesthetic, he was absolutely opposed to the practice. The narcotic effect of the drug often seemed to be doubled under these circumstances, and, besides, the patient might have an idiosyncrasy which would render it highly dangerous. He was also strongly opposed to giving whisky by the mouth, especially because it tended to promote vomiting. If alcohol were employed at all, it should be given by the rectum.

**Reply to Criticisms.**—Dr. Kemp said that while there might be some differences between the human heart and that of the dog, the similarity was sufficient, he thought, to justify the opening of the thorax and performance of cardiac massage in any patient in whose case the ordinary means of resuscitation had failed. In regard to Dr. Morris's suggestion, it seemed to him that as abdominal operations themselves were a frequent cause of shock, it would not be a very wise policy to open the abdominal cavity when the patient was already prostrated with shock. As to collapse of the lungs, he believed it was positively necessary to prevent this on account of the special relations which these organs bore to the heart, and that the maintenance of artificial respiration was therefore an important part of the procedure. In many cases of anesthesia syncope artificial respiration was of itself sufficient to restore the action of the heart. Collapse of the lungs was consequently a real danger. He was sorry to disagree with Dr. Bennett in regard to the question of inversion of the patient. It was a well-known fact that there is no better stimulus to the medullary centers, both cardiac and respiratory, than an increased blood supply, and the inverted position tended to promote this. If the patient was in a condition to respond to such stimulus, this of itself might start up heart-action.

## THE NEW YORK ACADEMY OF MEDICINE.

### SECTION ON GENITO-URINARY SURGERY.

*Stated Meeting, held May 20, 1903.*

John Van der Poel, M.D., Chairman.

**The Choice of Technic in Operating Upon Prostatic Obstruction.**—Dr. Chas. H. Chetwood read this paper, which will appear in a subsequent issue of the MEDICAL NEWS.

**Personal Results Obtained by the Bottini Operation.**—Dr. Willy Meyer, of New York, read this paper, and drew the following conclusions: (1) The operations making a direct attack upon the enlarged prostate gland were preferable to those aiming to exert an indirect influence. A direct attack should first be made in the case of every patient asking for relief. This failing, an operation on the testicles or vas deferens might then be resorted to: (2) Two useful operations were had for the direct treatment of the enlarged prostate, *i.e.*, prostatectomy and galvanocaustic prostatotomy (Bottini's operation); (3) In selecting the method indicated in any given case, one must individualize and be guided by anatomical, pathological and social conditions; (4) Prostatectomy was, of course, the most radical and most surgical procedure; it should be the operation of choice whenever promising success; (5) Perineal prostatectomy offered advantages over the suprapubic method, since it enabled the operator to do the operation under the direct guidance of his eyes. (6) Debilitated patients who seemed unfit subjects for the more radical operation should not be relegated to catheter life, nor should prostatectomy be done to "let them down easy;" they should be advised to have Bottini's operation performed. (7) Surgeons should familiarize themselves with both methods in order to be in a position to do justice to their patients. (8) It was the duty of those refusing to do Bottini's operation under any circumstances, to nevertheless advise patients who asked for more radical relief to have Bottini's operation done, if the operation with the knife seemed contraindicated. (9) The records of 59 patients upon whom he had operated, ranging in age from forty-seven to eighty-two years of age, 7 of whom died, either directly or indirectly from the operation, while 52 had recovered to a greater or less extent, were instructive. Much could be learned from these carefully elaborated statistics and further carefully compiled statistics as to the late results of both operative procedures—preferably in the hands of one man—were desirable in that they would increase our knowledge with reference to the selection of the proper method in the individual case.

Dr. Parker Syms said that the Bottini operation had always appeared to him to be a thoroughly unsurgical procedure and notwithstanding the claims made for it as regards its safety, he claimed it to be far more dangerous than the perineal prostatectomy and, at the same time, an operation which was not radical, inasmuch as it would only afford permanent relief to a few or small percentage of the cases. Years ago the profession came to the definite and proper conclusion that internal urethrotomy could not safely be applied to the deeper portions of the urethra. Certainly if that is true it is still more true that the electrocautery incision of the prostatic urethra, if done at all, should not be done by the internal method and, therefore, the speaker felt that the operation presented to the profession by Chetwood was far safer than that of Bottini. Dr. Syms claimed that prostatectomy done entirely through the perineum by the straight median incision was the safest means of affording definite relief to these sufferers. His own experience embraced 25 cases with but one death and he felt that, by his method of operating, any hypertro-

phied prostate could be removed through the simple median incision. In speaking of the mortality in the treatment of prostatic obstruction he made the statement that in those who had come to catheter life on account of this prostatic obstruction and acccompanied by cystitis, the mortality was 100 per cent. unless they were relieved by radical operation. With reference to the enucleation of the prostate he referred to his twenty-third case as an extreme example of celerity. This was a patient who had suffered from stone and who was in a very feeble condition and would not have been operated upon had he not required relief from this stone. He performed a perineal incision, exposed the prostatic urethra and apex of the prostate, opened the membranous urethra and, through that opening, performed a litholapaxy. Finally the anesthetizer suggested that the operation should be terminated quickly as the man's condition was failing. He then proceeded to enucleate the prostate at once and he was informed by one of the spectators that an absolute enucleation of the prostate in this case was accomplished in 45 seconds. He said that the operation ordinarily required from 30 to 45 minutes. In conclusion, he wished to pay a tribute to the admirable and unselfish work of Dr. Willy Meyer, who had made such unprejudiced investigations as to the merits of the Bottini operation. He felt that the medical profession was indebted to Dr. Willy Meyer for the results shown, though he always felt that the results showed the operation to be a dangerous and uncertain procedure.

Dr. Howard Lilienthal said that in dealing with hypertrophied prostates "doctors disagreed" and that in reply to the query "Who should decide?" he believed each doctor should decide for each case. Undoubtedly good results had been obtained by various methods and he believed that when a surgeon has been fortunate in the employment of one method and has become skilful in one particular operation, he was likely to continue employing that method or operation. It seemed to him that Dr. Sims took rather a narrow view when he insisted that *perineal* prostatectomy was the only form of prostatectomy to be employed. He agreed with Dr. Syms in believing that the operation of prostatotomy was not, as a rule, one to be recommended in all cases of prostatic enlargement. He believed, however, that in retention due to fibrous ring-like obstruction, in which hypertrophy plays no true part, prostatotomy might be employed with benefit. Dr. Lilienthal said he had had excellent results from suprapubic prostatectomy but he would be willing in proper cases to give the perineal method a trial. He asked Dr. Willy Meyer why he believed that section of, or injury to, the ejaculatory ducts caused impotence? It was his opinion, based upon clinical observation, that section of the ejaculatory ducts might cause sterility but did not cause impotence. Dr. Lilienthal said he had operated upon 14* cases, by the suprapubic method and had succeeded in curing 13 of the patients, so that they urinated normally and could completely empty the bladder. Some of the patients had suffered from stone and many from cystitis before the operation. One patient, himself a physician, had been operated upon one year before by the Bottini method with only temporary relief. When he first came under the speaker's observation there was complete retention and constant leakage. It was thought possible that the symptoms might be due to locomotor ataxia from which the patient suffered, this opinion having been given by a leading neurologist. On opening the bladder it was found that a median pedunculated lobe had been sagittally split into two equal parts by the Bottini incisor and these two parts fell together over the internal orifice of the urethra causing as complete retention as if they still consisted of one piece. This man made a perfect recovery and when Dr. Lilienthal saw him a few days ago he could completely empty his bladder and voided limpid normal urine. Suprapubic prostatectomy could be performed with great rapidity and the entire operation finished in from twelve to thirty minutes. Usually not a single vessel has to be tied, no vascular structures being divided. The incision was made in the median line through the linea alba and then into the bladder previously distended with air. In his later operations Dr. Lilienthal had avoided the use of counter-drainage in the perineum and he believed that this counter-drainage, in the presence of good siphon drainage from the suprapubic wound, was unnecessary and even harmful. The patient who died was uremic, partly aphasic before the operation, and this operation was done for complete retention. He believed that, in this case, it would have been wiser to have been satisfied with suprapubic drainage until the patient's general condition should have been improved when a prostatectomy would have been probably fraught with less danger.

Dr. James Pedersen said that recent literature showed some desertion from the Bottini operation in favor of prostatectomy, and a tendency to favor perineal prostatectomy as opposed to suprapubic. He inclined to the belief that, taking all operators and all cases into account, the Bottini operation was less serious than prostatectomy. He thought that an effort should be made to classify cases, and to regard some as better suited for prostatectomy than for the Bottini operation. In this the cystoscope is of the greatest help. He was inclined to favor freer drainage of the bladder in some cases after the Bottini operation than can be obtained by an inlying catheter of usual caliber, and therefore approved of Dr. Chetwood's perineal galvanocautery prostatotomy. He is convinced that certain cases could be greatly benefited, if not cured, by the Bottini operation, which certainly would not survive a prostatectomy.

Dr. Joseph Wiener, Jr., said that he had fortunately been able to see most of the cases operated on by Dr. Lilienthal, and had been persuaded by the good results obtained, to perform suprapubic prostatectomy in his own cases. Not only was the mortality low, only four per cent., but the patients that had survived the operation had all been absolutely cured. In not one of the cases was there pain or residual urine present after the wound had healed. Dr. Wiener emphasized the fact that if some of the previous speakers had seen the remarkable results attained by the suprapubic operation, they could not have made some of their statements. The statement had been made that prostatectomy should only be done when promising success. Suprapubic prostatectomy promised success in 96 per cent. of unselected cases. Moreover, the statement that debilitated subjects should not have a prostatectomy done was not borne out by experience. Dr. Wiener had performed suprapubic prostatectomy in a man of eighty-two years, and the patient had made a perfect recovery. Moreover, he had recently performed the operation, with gratifying results, under laughing gas anesthesia. The former of these operations had been done in fourteen minutes, and the latter in eleven minutes. Comparing the results of suprapubic prostatectomy with those of the galvanocaustic operations, the doctor said that he could not see why the latter operations, which in many cases were merely palliative, should be done, when the mortality following them was much higher than that following prostatectomy. In comparing the suprapubic operation with the perineal, the doctor said that he favored the suprapubic on account of the better exposure, and

* Dr. Lilienthal regrets to note an error in the figures originally given, namely, 23 cases. The error was a clerical one and was due to certain cases of malignant and suppurative disease having been counted in.

more especially on account of the rapidity with which it could be done. Dr. Parker Syms had said that it took from thirty to forty-five minutes to do the perineal prostatectomy. The suprapubic operation could always be done in one-half, and often in one-third of that time. Moreover, Dr. Wiener had been enabled to perform suprapubic prostatectomy without the use of ether or chloroform, and that, in old subjects, was surely a decided advantage.

Dr. Chetwood said there was nothing else for him to add, unless it was to reiterate the facts he had already brought out. He would dissent from the suggestion that the galvano-cautery operation was in anywise a palliative measure. It had been demonstrated in many of his cases that its effect was most radical. When several patients—not one case—who had been suffering from chronic pyelonephritis of an advanced type were operated upon by the method in question, the obstruction in the bladder relieved and complete abatement of the pyelitis followed, such a result could not be looked upon as palliative, but was most radical. When a large number of cases of complete and incomplete retention of urine, operated upon by the same method, were able to dispense with the use of the catheter and were relieved entirely of their retention, such a result could hardly be called palliative. He would not pretend to say that prostatectomy was not the operation of choice in some instances; but that there were many cases unsuited for this operation—cases of bar formation, of hard, fibrous enlargements, which could not be enucleated, that were better attacked by means of the galvano-cautery—could not be denied. He said that the reports heard, which gave so low a mortality, were very impressive, but could not be accepted as final in face of the incontestable statistics of other well known operators. There was one cause of death which always was a possibility, no matter how skilful the operator or how short the operation; and that was pulmonary or cardiac embolism, the chances of which were certainly much greater where glandular tissue was removed. He had seen a number of such cases. He felt that he could take to himself a part of the credit of the success of the evening, although he had personally contributed the least share toward it; as, on the invitation of the President, he had dictated the subject discussed, and it had been on this account that the President had extended the invitations to the gentlemen who had read papers and participated in the discussion.

Dr. Willy Meyer thanked Dr. Syms for his words and said that he had purposely followed up the Bottini operation tenaciously for five years to the exclusion of all other methods in order to find out *by personal experience* whether it had a place in the radical treatment of prostatic hypertrophy or not. As the result of such an experience he came to the conclusion that it had. He said that as much as he agreed with him that deaths that followed any operation should be counted as deaths due to that operation, still he could not do so in glancing over his own cases. Thus, if a patient, who had been operated upon by the Bottini method, developed for some unknown reason an acute phlebitis of the left saphenous vein and after having been thoroughly relieved from urinary retention died after a while from a pneumonia which, though no post mortem was made, was thought to be embolic, it would have been unjust toward the Bottini operation to count that case as one due to the interference as such. Further, if, in testing the Bottini operation, one tried to find out the best method of procedure for using spinal anesthesia with a sterilized solution of tropacocaine and the patient immediately after the injection and before the operation as such had been finished, showed symptoms of general interference with his well-being and died within the next few days with the same symptoms, it was also unjust to attribute such a death to the Bottini operation as such.

With regard to the question of radical relief of the prostatic trouble by means of galvano-caustic prostatotomy he said, that he had presented several patients to the New York Surgical Society and to other medical gatherings, to prove the effectiveness of this method of treatment. A number of patients thus operated upon had had no pain in urinating, emptied their bladders four or five times in twenty-four hours, and had less than one to two ounces of residual urine. In fact they felt perfectly well and cured. Therefore, he believed, it was absolutely incorrect to call the Bottini operation a palliative procedure as had been done by Dr. Wiener. He said that it was true that, in a number of cases, the operation would not cure but bring relief only, but this was not the fault of the operation but of the operator. As had been mentioned in the paper, Bottini's operation was a very difficult procedure with reference to carrying it out *properly* in a given case. Just as well the operation of litholapaxy might be termed a palliative operation because sometimes splinters of stone remain between the rugæ, were detected by the cystoscope later, and then crushed again or washed out at another séance. And yet, he said, litholapaxy was the operation of choice in operations for stone in the bladder. Of course it was much simpler for the surgeon to do a cutting operation and be able to immediately arrange it so, that the after-treatment can be taken care of by an assistant; but he said every surgeon would occasionally meet with patients in whom prostatectomy was absolutely contra-indicated. He knew there were colleagues who would refuse to recognize any procedure but prostatectomy. They would condemn such poor sufferers to the continual use of the catheter if they would not deem prostatectomy advisable, because, they say, there be no other choice for them. Whereas, he who knew that there is another operative procedure besides prostatectomy, viz., Bottini's operation, can probably help, nay even cure such an unfortunate patient. Surely only those who have done Bottini's operation only once or twice or not at all are the ones who condemn it.

Dr. Meyer said that so far he had not performed the modification of the Bottini operation, as proposed by Dr. Chetwood. Perhaps he was too conservative. But just as much as we were doing litholapaxy by introducing a lithotrite through the entire length of the urethra galvano-caustic prostatotomy could be successfully done in this way. He said it was true that in a few instances perineal section had become necessary later, because the galvanocautery knife had entered into the membranous urethra causing a periurethral abscess. Of course, such abscesses were not likely to develop if perineal drainage had been primarily established. However, if such an accident had occurred incision can be made in time and further injury be prevented. In many cases of large prostatic growths a finger of the usual size will not succeed in palpating very thoroughly the configuration of the gland, thus helping one in determining what should best be done for the patient at the moment. So far as drainage was concerned he was satisfied that a permanent catheter of from 15 to 19 French gauge induced through the entire length of the urethra was almost always well borne and necessary, sometimes for a number of weeks. He said that perhaps he might change his opinion regarding the modification of the original Bottini method as time advanced and that certainly Chetwood's results were gratifying and corroborated what he had said before, *i.e.*, that the Bottini operation could *not* be called a palliative procedure. He said that what would be necessary in the future would be to learn by careful analysis of every case how to indi-

vidualize in proposing operations and find out what was best to adopt in a given case. Before closing his remarks, Dr. Meyer asked that permission be given him to illustrate what he meant to say by a few cases as follows:

*Case I.*—A patient came from out of town; he had to work hard. He came under the speaker's care with an enlarged prostate associated with stone, and it was necessary to cure him, if possible, in one sitting. He had a very pronounced emphysema and chronic bronchitis. He did a perineal prostatectomy, removing the stone through the same incision, under spinal anesthesia with perfect success.

*Case II.*—Another patient in the sixties was brought to his office on account of prostatic trouble and with the statement that he and his wife were absolutely opposed to any cutting operation and that the patient was willing to continue the catheter throughout the remainder of his life if nothing else was feasible. He proposed the Bottini operation which he performed soon after. About ten weeks later, upon inquiring regarding the patient's condition the latter wrote him (he being a German), "I am famous" (famos). The catheter had been laid aside.

*Case III.*—A gentleman who had mining interests in the West and who traveled a great deal and who felt that he could not always have a doctor's help when needed, wanted the most radical work done. Perineal prostatectomy was proposed, accepted and performed. He now had not a drop of residual urine; now and then there was some little dribbling during night. He had some contraction at the neck of the bladder which was overcome by sounding.

*Case IV.*—Another patient in his sixties had a large amount of residual urine due to an enlarged prostate. Prostatectomy was proposed and accepted. Before operation a general examination of the patient revealed a pronounced valvular disease of the heart, so much so that after consultation general anesthesia as well as spinal anasthesia seemed contra-indicated. Inasmuch as the Bottini operation can be and ought to be carried out under local anesthesia that operation was proposed and done with much benefit to the patient.

*Case V.*—A patient, eighty-two years old, was brought to him suffering from far advanced paralysis agitans, with contracted hip-joints and absolute retention. His widowed daughter had been taught how to catheterize her father as the people were too poor to afford the continuous services of a trained male attendant. After months of faithful work the daughter had broken down and then the question came up as to what could be done for the patient. As a matter of course he was opposed to performing the Bottini operation on this patient. But the relatives insisted upon more than palliative work, being willing to take any risk. Thus Dr. Meyer reluctantly, in the summer of 1902, did a Bottini operation on this patient. A very troublesome after-treatment followed. The result was that the patient got rid of his catheter absolutely and has but very little trouble with his urinary organs. He said that truly a great boon had been conferred upon the patient and the entire family by having done Bottini's operation. The poor old man could now at least die in peace.

What the doctor wanted to bring out in writing his paper, was: *not* to discuss the uniformly recognized value of the two excellent cutting operations for prostatic enlargement, suprapubic as well as perineal, but to prove by his personal experience in 59 patients that, in especially selected cases, where prostatectomy by either route is contra-indicated or refused by the patient or his relatives, the Bottini operation must be proposed, inasmuch as it too could not only bring relief but perfect cure of the prostatic trouble.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, held May 23, 1903.*

The President, James Ewing, M.D., in the Chair.

**The Dysentery Bacillus in a Series of Cases of Infantile Diarrhea.**—Dr. Martha Wollstein read a paper on the results obtained from the examination of the stools of 114 cases for the bacillus of dysentery. The technic used was that recommended by Dr. Flexner and his pupils. The stools were obtained as fresh as possible. Where blood and mucus were present some was carefully taken on a sterile swab or platinum loop and suspended in natural broth of peptone water. From this suspension agar plates were poured at once or within an hour. Duval found that the dysentery bacillus grew more profusely on agar that is slightly acid in reaction and throughout this work such a medium was used. After the plates had been in the thermostat for twenty-four hours a number of glucose agar tubes were inoculated from them, and twenty-four hours later the gas-producing organisms were rejected. From the tubes without gas, transplants were made to plain acid agar, and then the bacilli were tested as to their reaction with serum from a horse immunized with the Flexner Manila organism.

Stools from healthy infants were examined in ten cases and dysentery bacilli were found. The stools from ten newly-born infants were also examined during a period of from twelve hours to eight days after birth. In no instance was the dysentery bacillus present. Of the 114 cases studied, the dysentery bacillus was found in 39. The ages of the children varied from five weeks to four years. The character of the stools varied greatly; blood was present in 20, usually as small specks mixed with or streaking the mucus. Many stools consisted entirely of blood and mucus. In five cases tenesmus was marked. Of the fatal cases the greater number died during the first or early in the second week. Only three lived for four weeks or more. The bacillus isolated was a short, non-motile rod with rounded ends, sometimes almost coccoid in form, growing singly or in pairs. Two cultures formed a thin pellicle in broth after five days, comparable to that described by Hiss in the case of his Bacillus "Y." Indol was formed in dextrose-free broth after three to seven days. One bacillus formed no indol and did not ferment mannite, maltose or raffinose. All the 38 other forms formed acid in the presence of mannite, raffinose, and maltose, as well as levulose, galactose and glucose. The agglutination reactions were fairly uniform and the bacilli reacted with a serum prepared from the Flexner Manila bacillus in dilutions of 1 to 50 up to 1 to 3,000; and with a serum prepared from the Shiga bacillus up to 1 to 200 only. Blood reactions were somewhat irregular. They were absent altogether in 12 cases. In six others the blood could not be obtained. In 14 good reactions were obtained. In seven cases the reaction was present only after the injection of antidysenteric sera, the blood having been negative before that time. The reactions were made with the bacilli obtained from the case, and with the stock "Harris" and "Shiga" cultures. No reaction was obtained in the blood in any case with the Shiga organism. One hour was the time limit used. The *Bacillus dysenteriæ* was not found in the heart's blood or in any viscus in five cases examined post mortem. A septicemia due to the *Bacillus dysenteriæ* seemed to be of rare occurrence.

In conclusion the speaker summed up as follows: Cases of infection with the dysentery bacillus in infants tend toward the clinical picture of dysentery, with frequent mucous and bloody stools. In some cases of hospital infection, occurring as terminal to other diseases (especially pneumonia) and in other mild cases,

the stools may never contain blood, but mucus is present in every case and usually in large amount. The serum reaction is uncertain during the first week, frequently negative after the sixth day, but may be absent for two weeks. It cannot be relied upon for early diagnostic purposes in infants and young children. The isolation of the *Bacillus dysenteriæ* from the stools is the only positive evidence of infection during life. The bacilli are present in the stools for a period of two to three weeks, but may remain for a longer time. The type of the organism almost invariably found in New York is that of the "Harris Manila" or Flexner bacillus.

**The Pathological Anatomy of a Series of Cases of Infantile Diarrhea in Which the Dysentery Bacilli Were Present.**—Dr. John Howland reported the results of autopsies on 17 young children suffering from infection with the *Bacillus dysenteriæ*. In the majority of cases bacteriological examinations were made antemortem; in three cases where the condition had not been suspected during life the bacteriological study was post mortem. The organisms found corresponded in all cases to what is known as the Flexner Manila or indol producing dysentery organism. In eight cases cultures were made from all the organs at autopsy; but in no case was the bacillus found except in the intestinal tract. In one case, the liver contained *Streptococci*. The other organs remained sterile or showed only the colon bacillus, with the exception of the lungs which often showed a great variety of organisms. Fifteen of these 17 children developed the infection while in institutions; two were suffering from the disease at the time of admission. The cases could be divided clinically into four classes: Acute, subacute, cured (death being due to another condition developing later) and terminal infections. There were no chronic cases. The acute cases were those which were fatal in ten days or less from the beginning of the characteristic intestinal symptoms. These cases were more apt to show blood in the stools than were the subacute cases, and were accompanied by a more marked rise in temperature, though this was not the invariable rule. There were seven acute cases in this series, one showing a pseudo-membranous enteritis; one a marked necrosis and ulcerative process; and one in which there was merely intense congestion with beginning ulceration and necrosis. The detailed study of the post-mortem findings showed that as a result of the infection with the dysentery bacillus there was a great variety in the pathological conditions found. Acute cases and terminal infections showed usually very marked congestion, more or less deep necrosis and ulceration. The cellular infiltration of the mucosa was irregular; but in general the more acute the process the more pronounced the infiltration. The same was true of the edema and infiltration of the submucosa. The infiltration of the mucosa was largely polynuclear, while in the submucosa mononuclear cells predominated. In only two cases was the muscular layer affected, and then but slightly. The peritoneal coat was involved in only one case. In one of these acutely fatal cases the lesion was what would be usually considered as subacute; that is, slight congestion, no ulceration, except through the follicles which were excavated and showed moderate hyperplasia. Of the three cases classed as subacute by reason of the duration of the disease, two exhibited the same lesions as the acute cases, though to a less degree; while in the third the hyperplasia and depression of the follicles was the prominent condition and the mucous membrane was not necrosed. Microscopical examination of the tissues for organisms gave nothing characteristic. In the necrotic areas, bacilli negative to Gram of the proper form and size were found in enormous numbers, both in the acute and in the subacute cases; but cocci and bacilli positive to Gram were also very abundant. Usually the organisms were present in considerable variety, and did not penetrate deeply into the mucosa; but in one case they were present in the superficial portion of the submucosa. Both ileum and colon were usually affected, changes in the latter being most marked. In three cases, however, the ileum suffered the most, and in one of these, a pseudomembranous case, there was hardly any change in the colon. It is interesting to compare at this time these cases with the Manila ones in adults described by Flexner, the specific germ being the same. He found the histological lesions in the mucosa to consist chiefly of coagulative necrosis with exudation of fibrin and polymorphonuclear cells. In Dr. Howland's cases the necrosis and the polynuclear cells were present but no fibrin could be demonstrated, though special staining was done for this. Flexner found the submucosa always much altered, swelling, hemorrhages, fibrinous and cellular infiltration, and he said that the changes might take place beneath an intact or almost intact mucous membrane. In contrast to this, the cases described by Dr. Howland showed no hemorrhages or fibrinous infiltration and the swelling and accumulation of cells never took place except beneath a very much altered mucous membrane. The conclusions in regard to the organisms agreed; though in one of Dr. Howland's cases bacilli were found in the submucosa where Flexner has said he never found them.

From a consideration of these 17 cases it appeared that in those terminating acutely, marked congestion, ulceration, or superficial or deep necrosis is the rule, even though the disease had lasted as short a time as two days, while in the subacute cases the changes were more catarrhal in character, with an increased follicular hyperplasia: in other words, the pathological findings were determined more by the severity of the infection than by the length of time that the disease had lasted—a severe and overwhelming infection producing destructive changes rapidly, the clinical course being correspondingly acute and short; while a less severe infection was the cause of catarrhal processes with slight destruction, the clinical course being correspondingly long.

**Reaction to Different Sugars.**—Dr. Philip Hanson Hiss congratulated Dr. Wollstein and Dr. Howland on the interesting reports which they had made. There were several questions which he would like to ask Dr. Wollstein. She had spoken of the organisms falling into two groups: one group similar to the Shiga bacillus, and the other large group composed of organisms able to ferment many carbohydrates—mono-, di- and poly-saccharids—with the production of acid but not of gas. He would like to know how Dr. Wollstein had made her fermentation tests and what the source of her sugars had been. In the few cases which he had had the opportunity of examining he had found two groups of organisms, leaving the Shiga type out of the question, and he considered that unless the fermentation tests were very carefully made and the purest sugars were used that this difference might not be shown. Maltose at the best was very uncertain, and all the forms of organisms if left long enough in it would probably give rise to fermentation. These two groups were distinguished from the Shiga organism by the fermentation of mannite and from each other by the fermentation, in the case of the more active fermenters, of dextrin and saccharose. The less active group fermented mannite but could not utilize dextrin and saccharose. Dr. Hiss thought the careful study and separation of these organisms very necessary because this report included a large series of cases histologically studied, and if anything was to be made out about the connection of these organisms with the different types of disease this

was the only way to do it. Dr. Hiss considered it not unlikely that in other series of cases of dysentery and diarrhea studied in this country, the organisms had not in all instances been preserved, as it had been thought, from the methods of study then used in their identification, that they were of the true Shiga and Kruse type. Hence, the frequency of occurrence of the different groups and their relation to the different types of gastro-intestinal disease in which they occurred could not now be determined. He therefore wished to ask Dr. Wollstein how she had made her fermentation tests and whether she had attempted to establish the etiological relationship of the different groups of organisms to the various types of disease which Dr. Howland had determined.

Dr. Augustus A. Wadsworth asked Dr. Howland if he had used any stain beside the Gram for demonstrating the organisms in the lesions. Were any of the tannic acid stains used?

**Shiga Bacillus and Dysentery.**—Dr. James Ewing said that while it was perhaps a little late to raise a question regarding the existence of infection by the bacillus of Shiga in many cases of infantile diarrhea, yet it seemed to him that the relation between the disease and the bacillus had not been fully demonstrated in these valuable papers. It seemed to be a matter of importance to know in what relative abundance the Shiga bacillus had occurred in the stools of these infants, since it was probably not the only organism in the stools. It would have been of interest to know the results of a systematic study of the serum reactions of these patients, not only on the Shiga bacillus, but on the colon bacillus and other micro-organisms which might have been isolated. Perhaps the serum of some of the patients might have proved quite as active on other bacteria of the stools as on the variety of Shiga bacillus isolated and tested. It appeared that much work of this sort was needed to definitely fix the relation of intestinal bacteria to these intestinal diseases.

Dr. Wollstein said that the sugar reactions were made with the sugars obtained from Merck and had been made in two ways. The glucose, lactose, saccharose, mannite and maltose reactions were made in fermentation tubes as well as in litmus agar prepared without meat. The other sugars were used in the sugar-free litmus agar. In regard to Dr. Ewing's remarks, Dr. Wollstein said that she did not think that it had been absolutely proven that the dysentery bacillus had been the only etiological factor in these cases and that she had therefore taken pains to call her report simply "The Dysentery Bacilli in a Series of Cases of Infantile Diarrhea." The dysentery bacillus had certainly been present in the stools of 39 cases, in greatest numbers in the cases with much mucus and blood. In the stools which contained more fecal matter they were often very few and difficult to isolate.

Dr. Hiss said in regard to the sugars, especially dextrin, that he had had specimens from Merck marked "highest purity," which in fermentation tests were little better than glucose and had acted practically as did glucose in all differential tests. Much dependence could not, therefore, be placed upon sugars bought in the open market, and it was necessary to test them thoroughly before depending upon results obtained with them.

Dr. Howland said that he had stained the bacilli with Gram-Weigert and methylene blue. He had not assumed that all these bacilli were dysentery bacilli, and had therefore called them "bacilli of the typhoid-colon form negative to Gram." Nor had he assumed that in all these cases death had been due to dysentery.

**Cretinism in a Cat.**—Dr. F. H. Miller presented this case because of the extreme rarity with which it was observed in veterinary medical practice, this being the first case he had seen in fifteen years of practice. The head of the animal was suppressed in growth and was very wide across the forehead in proportion to the size of the cat. There was a condition of exophthalmos which was very marked. The under jaw was about one-third short of the length of the upper jaw and the tremendous thickening of the bone made it impossible to close the mouth. There was no anchylosis. The animal showed the short limbs and overdevelopment of the muscular tissue very unlike that of the rachitical patient. Dr. Miller said that he had seen the animal for the first time when it was about two months old. While, of course, the head had since grown a great deal, it had been even at birth very abnormally large, having the great width between the eyes. The cat had been examined by several doctors and oculists, and injections of atropine into the eye had shown a great difference between it and the normal eye. The periphery of the optic nerve was very pale and the nerve disc was very markedly depressed. It was important to state that the intelligence of the cat was very subnormal. Its life was entirely a matter of comfort and taking things easily. The pelvis was normal, and the great difficulty was in the limbs from the knee and elbow-joints downward. The metacarpal bones were more or less normal. It was impossible to find any trace of the thyroids, though careful examination had been made. There was probably either obliteration or total absence of them.

Dr. Stuart Hart asked whether the thyroids were palpable in the normal cat.

Dr. Miller said that they were readily found, especially in a cat of this size. He believed that in this case they were entirely wanting. The cat could take food only with great difficulty. There was a tremendous thickening of the facial bones. The teeth were set in a semicartilaginous bone, not true bone at all.

**A Case of Rhabdomyoma of the Tongue.**—Dr. Harlow Brooks and Dr. Stebbins reported a case of rhabdomyoma of the tongue, which was so far as they knew the only case ever reported, the tumor being very rare in striated muscle. The patient was a Hebrew, born in Russia but resident in this country for some time. The family history was negative. Two years before he had had a broken tooth which projected and irritated his tongue on that side until it raised a small nodule which he had had cauterized and cut off with a pair of scissors. The tooth had then been taken out. After this time the enlargement had given him no trouble, though he could still feel it, until six weeks before the last removal, when it had begun to enlarge. The nodule measured about .7 cm. across, .6 cm. in width, and .3 cm. in depth. It was solid and very firm. Microscopically, it did not show the typical form of rhabdomyoma such as was generally found in the organs of the genital tract. Nearly all rhabdomyomas have originated from the organs arising from the intermediary cell mass, so that this case had a double interest. Some of the tumor cells showed striation fairly well. There was no doubt but that the cells were those of striated muscle, though most of them were of a more embryonic type. They had gone beyond the stage of unstriated muscle fibers. The case was particularly interesting because the tumor arose from an altogether different embryonal source than the ordinary rhabdomyoma.

## ORIGINAL ARTICLES.

### FETAL, CONGENITAL AND INFANTILE TYPHOID.*

BY JOHN LOVETT MORSE, A.M., M.D.,

OF BOSTON, MASS.

INSTRUCTOR IN DISEASES OF CHILDREN, HARVARD MEDICAL SCHOOL; ASSISTANT VISITING PHYSICIAN AT THE CITY HOSPITAL AND AT THE INFANTS' HOSPITAL, BOSTON.

ALTHOUGH much has been written in the past regarding this subject and many cases reported from time to time, yet, on account of the inherent difficulty of the diagnosis from either a symptomological or pathological standpoint, but little reliance can be placed on the earlier data and no satisfactory conclusions drawn from them. Since the accurate differentiation of the typhoid bacillus and the discovery of the typhoid serum reaction, however, a certain amount of trustworthy material regarding fetal and infantile typhoid has accumulated. Conclusions based on these later data are of some real value.

*Abortion in Typhoid.*—Abortion occurs in from 50 per cent. to 70 per cent. of the cases of typhoid. Various causes have been advanced for this frequency of abortion. Among them are (1) the high temperature, (2) the accumulation of toxins in the maternal blood, (3) the death of the fetus. It is probable that there is no common cause and that the etiology varies in different cases, any one of the above causes being amply sufficient to produce abortion. Most writers agree, however, that the death of the fetus is the most common cause. This may result from the high temperature, the passage of toxins through the placenta, or intra-uterine typhoid, the last being probably the most common.

*Fetal and Congenital Typhoid.*—Under the head of fetal typhoid are included the cases which are born dead or die at birth, while under the head of congenital typhoid are included the cases which are born alive and suffering from typhoid. This division is an arbitrary one and comparatively unimportant. The important consideration is whether the infection is intra-uterine or extra-uterine in origin.

In considering the question of intra-uterine typhoid infection it is necessary, in the first place, to throw out all the cases described before the discovery of the typhoid bacillus and all the conclusions drawn from them. Analysis of these cases shows that the great majority of them were certainly not typhoid, and in none of them is the evidence convincing. Moreover, some of those which are supported by bacteriological examinations are open to criticism, as they were studied before the differences between the typhoid bacillus and the colon bacillus were as well recognized as they are at present. A considerable number of cases, however, have been sufficiently studied to be worthy of analysis and to form the basis for certain conclusions. Fifteen of these have been proved by autopsy and cultures, and one by autopsy and an increasing serum reaction. Ten were born dead and six died in from five minutes to three weeks after birth.

*Giglio: Miscarriage in sixth week of typhoid of 3½ months' fetus. Numerous hemorrhages in placenta. Microscopically typhoid bacilli in intervillous spaces. Fetus macroscopically and microscopically normal. Cultures from spleen, liver, intestines and blood of fetus showed typhoid bacilli.

*Eberth: Abortion of four months' fetus at end of third week. No changes in placenta. Typhoid bacilli were found in the intervillous spaces. Fetus was born dead in unbroken membranes. No changes in fetal organs. Cultures of typhoid bacilli were obtained from the heart's blood, lungs and spleen.

Lynch: Miscarriage at end of second week of typhoid at four months. Microscopically the placenta showed numerous hemorrhages. Sections of the placenta showed no bacilli. Cultures from the fetal blood and "organs" showed typhoid bacilli. The maternal blood gave a positive Widal reaction in a dilution of 1 to 50. The fetal blood was negative in a dilution of 1 to 10.

*Neuhauss: Miscarriage of a four-months' dead-born fetus on fourth day of convalescence after a relapse. No note as to placenta. Autopsy immediately after birth. The spleen was not enlarged and the intestines showed neither ulcers nor swollen Peyer's patches. Cultures of typhoid bacilli were obtained from the spleen, kidneys and lungs. The liver was sterile.

Etienne: Abortion at fifth month on twenty-ninth day of disease. No placental lesion. Cultures from placental blood showed typhoid bacilli. All the fetal organs were perfectly healthy. Spleen not enlarged. Intestines normal. Cultures from splenic and hepatic pulp and heart's blood showed many typhoid bacilli.

Fordyce: Delivery at fifth month in sixth week of typhoid during a relapse. No note as to condition of placenta. Sections of placenta and umbilical cord showed no bacilli. Fetus died during delivery. Very careful autopsy. Everything normal except for a small amount of serous fluid in the peritoneal cavity. This fluid gave an almost immediate positive Widal reaction. Sections of the liver, spleen and kidney showed no bacilli. Cultures from the kidney and spleen showed typhoid bacilli answering all tests, including the serum reaction. Cultures from the intestinal contents and heart's blood were sterile. The heart's blood, however, gave a positive serum reaction.

*Reher: Abortion of six-months' dead-born fetus on nineteenth day. The placenta was not examined. The spleen and mesenteric glands were not enlarged. The intestines were normal. No bacilli were seen in smears and sections of the liver and spleen. Cultures were obtained from these organs.

Balp: A woman with typhoid—proved by autopsy four days after delivery—miscarried in the fifth week of a six-months' fetus. The blood of the placenta and of the fetal spleen showed typhoid bacilli and the *Staphylococcus pyogenes aureus.*

* Read before the New York Academy of Medicine, March 19, 1903.

Hildebrandt: Miscarriage at end of second week of seven-months' dead-born fetus. No note as to condition of placenta. A few typhoid bacilli were found in the placental spaces. The spleen was possibly a little enlarged. The mesenteric glands were not enlarged. There were a few prominent solitary follicles in the lower ileum, but they contained no bacilli. Typhoid bacilli were found in the smears from the spleen, liver, mesenteric glands and blood; in sections of the spleen and kidneys, and in cultures from the spleen, liver, mesenteric glands and blood.

Frascani: Miscarriage in fourth week of eight-months' macerated fetus. Numerous placental hemorrhages. Maternal splenic blood (obtained with syringe) showed typhoid bacilli in cultures. Blood from the fetal organs gave pure cultures of typhoid bacilli.

Freund and Levy: Abortion at six months in fourth week of typhoid. Delivery conducted under strict aseptic precautions. Placenta showed evidences of an old endometritis, but none of any recent, acute process. Cultures from placenta showed typhoid bacilli. Cultures from surface of placenta sterile. Child died in fifteen minutes. Bacteriological examination begun five minutes later. There was a slight hyperplasia of the spleen, which appeared a little softer than normal. The intestinal mucosa was normal. There was no ulceration of Peyer's patches. Cultures from the splenic pulp and the heart's blood showed the bacillus of Eberth. Cultures from the vernix caseosa were sterile.

Dürck: A woman with typhoid was delivered of a living child on the twenty-fourth day. The child died in nine hours. There was marked swelling of the liver and numerous hemorrhages beneath its capsule. The spleen was enlarged and congested and typhoid bacilli and staphylococci were found in sections. The other organs were normal. Cultures from the liver and spleen showed typhoid bacilli and the *Staphylococcus pyogenes albus.*

Ernst: Miscarriage at eight months on eleventh day. No note as to placenta. Fetus lived ninety-three hours. It showed no symptoms of typhoid. It was not nursed by its own mother. It had icterus and died suddenly. The intestinal tract was normal. Typhoid bacilli were found in sections of the spleen, muscles, heart-muscle and blood-vessels of the brain and femur. Cultures were obtained from the spleen and heart's blood.

Legry: Abortion at seven months on fourth day of a relapse. No note as to placenta. The child was born alive and died after four days in an incubator. The liver of the fetus showed the same lesions as did that of the mother. A culture of the typhoid bacillus was obtained from the fetal liver.

Janiszewski: Miscarriage at 8½ months on twentieth day. No note as to placenta. Infant died on fifth day. The spleen was normal. There were superficial hemorrhages in the kidneys. There was bronchopneumonia. The other organs, including the intestines, were normal. The spleen, kidneys, mesenteric glands and lungs showed many typhoid bacilli microscopically. They were also obtained in cultures from these organs and from a piece of intestine near the ileocecal valve.

Brown: Miscarriage at eleventh day of seven and a half months' fetus. The mother had a typical typhoid with a positive Widal reaction. The infant's temperature was 100° F. at birth. It rose to 103° F., where it remained for about two weeks, after which it fell gradually to normal. The spleen was palpable and the stools yellowish and loose. There was no tympanites or roseola. The infant died of inanition two days after the temperature reached normal. The age of the infant at death is not stated. It was presumably about three weeks. On the ninth day the blood gave a partial Widal reaction in thirty minutes and a complete one in forty-five minutes; on the sixteenth day it gave a positive reaction in ten minutes. The spleen was large and soft. The ileum showed healed ulcers with the characteristic shaven-beard appearance. The mesenteric glands were enlarged. No microscopic examination and no cultures were made.

These cases prove, without question, that the typhoid bacillus can pass from the mother to the fetus through the placenta. This fact has also been demonstrated experimentally by Chantemesse and Widal, Frascani and Remlinger. While there is no doubt that bacteria can pass from the mother to the fetus through the placenta, there is some doubt as to whether they can pass through the normal placenta. This question is, however, unimportant for our purposes.

Ten of these cases were born dead or died at birth. One died in fifteen minutes, one in nine hours, two in four days, one in five days and one in about three weeks. None of them showed any special symptoms beyond fever, but simply did not thrive and died. In the absence of the symptoms of any other disease and with the bacteriological evidence of typhoid infection, it seems reasonable to attribute their death to this cause. It is possible, however, that prematurity may have played a part in their early death.

Several other cases have been reported as examples of intra-uterine infection, or congenital typhoid fever. In estimating the value of these cases, however, it must be remembered that not every infant with fever born of a typhoid mother is suffering from typhoid fever, and that a positive Widal reaction in the infant does not necessarily mean typhoid in the infant, but may be due to agglutinin transmitted through the placenta. Rouslacroix's cases show how careful we must be in making the diagnosis of typhoid in the infants of women with typhoid:

Rouslacroix: Miscarriage of twins at eight months, near the end of the second week of typhoid. The mother's blood gave a positive Widal reaction, in a dilution of 1 to 100, fifteen minutes before the birth of the children. The mother died later. Both infants had edema of the face and legs from the second day. They also developed marked icterus. They did not vomit and had normal stools. The temperature of both rose nearly to 104° F. on the fourth day. One died on the fifth day and the other on the sixth day. The autopsy showed nothing abnormal in one and a little bronchopneumonia in the other. Cultures from the blood and spleen of one showed colon bacilli and no typhoid bacilli. The blood of both infants at birth and four days after birth was negative in a dilution of 1 to 10 after two hours.

The cases reported as congenital typhoid fever are as follows:

Bell: Full term labor two days after temperature had reached normal in an attack of typhoid showing a positive Widal reaction. The infant was apparently healthy at birth but developed a temperature at once. The next day it reached 103.4° F. It remained high for seven days, when it suddenly dropped to 100° F. From this time on it gradually declined. There was marked jaundice and very many rose spots. The tongue was raw, shiny and red, and finally fissured. Stupor

was marked. The baby was nursed by its mother. Its blood gave a positive Widal reaction on the second day, while the leucocytes numbered 15,000. Three positive Widals were obtained during the week. The reaction of the milk was not tested. Four months later the mother's blood gave no Widal reaction, while the infant's gave a positive reaction in a dilution of 1 to 20 in two hours.

*Westervelt: Miscarriage at the beginning of the third week of 7½ months' fetus weighing 3 pounds 14 ounces. The mother's blood gave a positive Widal reaction. Ten hours after birth the temperature was 103.5° F. During the next seventeen days it ranged between 102° F. and 99.2° F. During the next three weeks it ranged from 99° F. to 97.8° F. and the child gained in weight. At this time the child had a convulsion and the temperature rose to 106.4° F. After this it was normal. The spleen was much enlarged, the abdomen was distended and the child had diarrhea. There were no rose spots. The Widal reaction was not tried. The infant recovered.

*Chambrelent and St. Philippe: Miscarriage at eight months. The infant did not do well from the start. It was feeble, had a large liver with jaundice and developed bronchopneumonia. Presumably it died. It was not nursed and was taken from the mother immediately. The infant's blood and the serum from a blister gave a very marked positive Widal reaction. The day on which the reaction was obtained is not given.

*Johnston: An infant was found to have fever five days after birth. From this time until the end of its illness the infant had a continued fever. Presumably it died, although no statement is made to that effect. As the case was reported in a discussion of infantile typhoid it is presumable that the mother had typhoid, but no such statement is made. Tympanites and constipation. No roseola. Marked restlessness. An older child in the house developed enteric fever a short time later. No further data.

*Krim: Miscarriage at the end of the second week, a week before term. Widal reaction in mother not tested. Infant's temperature at birth was 102° F. and five hours later 103.5° F. It ranged at about these figures for seventeen days, when it fell to normal. The infant was bottle-fed and made a good recovery. No other data as to symptoms or Widal reaction.

*Oakey: A woman with typhoid was delivered of a child at about full term. It was feverish at birth and died in ten days.

While Krim's, Johnston's and Oakey's cases may have been typhoid they cannot be accepted as proved because the data is insufficient. Westervelt's and Chambrelent and St. Phillippe's cases probably were typhoid, but here again the proof is hardly convincing. Bell's case was almost certainly typhoid. The most convincing point is the presence of the Widal reaction in the infant four months later while it was absent in the mother. It could hardly have been transmitted to the infant through the milk, because, when thus transmitted, it persists but a short time.

It is evident, therefore, that the fetus most often dies in utero as the result of the typhoid infection. If it is born alive it usually succumbs rapidly to an acute cachexia without special characteristics. If it lives longer it may develop some of the classic symptoms of extra-uterine typhoid and may possibly survive the disease.

*Cases in which the proof, bacteriological or otherwise, is not positive.

In 12 of these cases the organs were carefully examined macroscopically and often microscopically as well. In four the spleen was somewhat enlarged; in two of these it was slightly soft and in one congested. In one there were a few prominent follicles in the lower ileum but they did not contain bacilli, and in Brown's case which lived about three weeks there were healed ulcers and enlarged mesenteric glands. In one the kidneys showed superficial hemorrhages. In one other case in which only the liver was examined it showed microscopic changes identical with those found in the mother's liver, and in one there was marked swelling of the liver and numerous hemorrhages beneath its capsule. These were the only pathologic changes found in all the cases. It is evident, therefore, that the lesions of the intestine and mesenteric glands so characteristic of typhoid in extra-uterine life do not occur in intra-uterine typhoid unless the patient survives some time after birth. These organs are almost invariably normal. The liver and spleen are sometimes enlarged, however, and hemorrhages may take place into different organs.

These differences in the pathology of extra-uterine and intra-uterine typhoid are probably due in part to the difference in the method of infection, and in part to the fact that the intestine is not functionating in fetal life. In the one instance the bacilli enter through the mouth, localize themselves in the intestine, and thence comparatively slowly infect the organism through the blood; in the other they enter the circulation directly through the umbilical vein and cause a general infection from the start. One is a primary, the other a secondary septicemia. The experiments of Netter and Levy show that in intra-uterine pneumococcus infection pulmonary lesions do not develop when the lungs have not functionated. A pneumococcus septicemia results instead. If the lungs functionate after birth pneumonia may develop. The comparatively marked changes in the intestine in Brown's case, which lived three weeks, are of interest in this connection. Mamoinski, moreover, found that the spleen of a fetus whose blood contained an abundance of the spirochætæ of relapsing fever did not show any characteristic changes.

The lesions of intra-uterine typhoid infection are, therefore, general rather than local. The cases of adult typhoid without intestinal lesions and of severe and even fatal cases of typhoid with very slight intestinal symptoms are of interest in this connection. The results of the bacteriological examinations in the reported cases are important as giving corroborative evidence of the general septicemic nature of the infection in the fetus. Cultures were made in every case but one, but unfortunately not from all the organs in every case. Typhoid bacilli were found in the spleen in every instance in which cultures were made, and in the heart's blood and liver in all but one. They were found in the liver in nine cases, in the kidney in five, in the lungs in five, in the mesenteric glands in two and in the intestines

in two. Blumer's case, which developed in the three-days' old infant of a woman who had had typhoid when 4½ months pregnant, is interesting in this connection as showing the septicemic nature of the infection.

Blumer: Typhoid in fifth month of pregnancy. Full-term labor. Infant normal at birth. Three days after birth infant developed convulsions, which continued. On the fifth day bleeding began from an erosion of the cervix and continued. Death on ninth day. The autopsy showed hemorrhages into the kidney, bladder, vagina, uterus, esophagus, intestines and mesenteric glands. There was swelling of the spleen and cloudy swelling of the liver and kidneys. There was a follicular colitis and ileitis. The histological findings in the organs were those described by Mallory in the typhoid of adults, but less in degree Cultures from the heart's blood, liver and kidney were negative. Those from the lung, umbilical cord, bile, spleen and contents of colon contained typhoid bacilli. Blumer thinks that the typhoid bacilli must have remained latent in the fetal tissues for four and one-half months and then suddenly became disseminated, causing the septicemic type of the disease. He thinks that the disease developed too soon for infection from outside. The infant was breast-fed and the mother's urine contained no typhoid bacilli.

The septicemic nature of the infection accounts for the extreme mortality in fetal and congenital typhoid. This mortality may, however, be more apparent than real as it is possible that a certain number of the infants which are born alive and well after typhoid fever in the mother may have had the disease in utero. A positive Widal reaction has been found in the blood of several infants born under such conditions. Unfortunately, however, this cannot be accepted as proof of intra-uterine typhoid, as the agglutinating power may have been transmitted from the mother through the placenta, the fetus not having had the disease. The case of Etienne's, in which the serum reaction was stronger in the fetal than in the maternal blood, does seem to suggest, nevertheless, that the fetus may survive an intra-uterine infection.

Etienne: A woman, five months pregnant, died on the fifteenth day. She did not miscarry. The fetus died as the result of her death. All the fetal organs were normal and cultures from its heart's blood, liver and spleen were sterile. The fetal heart-blood gave a positive Widal reaction in a dilution of 1 to 200, while that of the mother reacted only in a dilution of 1 to 150. He concludes, and it seems justly, that as the agglutinating power of the fetal blood was greater than that of its mother it did not pass from the mother to the fetus through the placenta, but was produced by the fetus itself. This may have been as the result of a previous intra-uterine infection or in response to toxic absorption through the placenta. The absence of typhoid bacilli in the organs is consistent with either explanation. The latter seems the more probable, however.

This case seems to be the only one which in any way goes to show that recovery from fetal typhoid ever occurs. There are many cases on record, however, which prove that infection of the fetus is not a necessary result of typhoid in the mother. Among these are those of Frascani, Charrier and Apert, Osler, Etienne, Fraenkel and Simmonds, Darling, Wilson, Ker, Griffith, Morse, Plauchu and Gallavardin, Jehle, Mahrt and Rouslacroix.

The following conclusions regarding fetal and congenital typhoid seem justified:

1. The typhoid bacillus can transverse the abnormal, and possibly the normal, placenta from mother to fetus. Other organisms may also pass in the same way.

2. Infection of the fetus results. Because of the direct entrance of the bacilli into the circulation, intra-uterine typhoid is from the first a general septicemia. For this reason, and probably also because the intestines are not functionating, the classical lesions of extra-uterine typhoid are wanting.

3. The fetus usually dies in utero or at birth as the result of typhoid infection.

4. It may be born alive, but feeble and suffering from the infection. If so, death usually occurs in a few days without definite symptoms.

5. If it lives longer it may develop some of the classical symptoms of extra-uterine typhoid infection and at death may show some of its pathological lesions. Death is the usual result, but certain imperfectly reported cases suggest, if they do not prove, that recovery may take place.

6. It is possible that the fetus may pass through the infection in utero and be born alive and well. There is, however, no proof that this happens.

7. Infection does not always occur. The pregnant woman does not necessarily transmit the disease to her child.

*Infantile Typhoid.*—A number of years ago there was much discussion as to whether or not typhoid fever ever occurred in infancy. This discussion was soon settled in the affirmative. Since then, however, there has been much difference of opinion as to the frequency of typhoid in infancy, that is, in the first two years of life.

There is no very evident reason why the infant should be less susceptible to typhoid infection than the adult; in fact, judging from his greater susceptibility to bacterial infection in general, he should be more so. The exposure during the first year, when the infant is usually fed on breast milk or some cooked food, is undoubtedly less than in adult life. In the second year, however, when it is fed largely on raw milk it should be greater, exposure through water being the same in both cases. Nevertheless, statistics in epidemics and in large series of cases apparently show that typhoid is very uncommon at this age. On the other hand, several large series of cases, some of which reach into the hundreds, have been collected from literature. These series prove, what no one at present denies, that typhoid fever occurs in infancy. They also prove that the literature of the last fifty years contains the reports of a considerable number of cases of typhoid in infancy. Granting that all the cases reported as typhoid really were typhoid, these few hundred cases are insignificant in comparison to the thousands of cases which have been reported in adults

during the same time. Thus, instead of proving that typhoid occurs frequently in infancy, they merely serve to emphasize its apparent infrequency. It cannot be granted, however, that all the cases in these series really were typhoid. In many the diagnosis is most certainly incorrect, and in more doubtful. When these incorrect and doubtful cases are eliminated, as they should be, the apparent infrequency of typhoid in infancy becomes even more evident. A striking thing about the cases which certainly were typhoid is the large proportion of them which occurred in connection with other cases in the same house or during severe epidemics. This suggests that infants contract the disease only when the exposure is considerable.

There can be but two interpretations of these figures: either typhoid fever is relatively uncommon in the first two years of life, or it is not recognized when it occurs. If it is not recognized when it occurs it must be because the disease at this age does not resemble the type seen in older children and adults, and hence is mistaken for some other condition.

Three methods are available for determining the type of typhoid in infancy: (*a*) Analysis of the previously reported cases in which the diagnosis is proved by a positive Widal reaction or by the cultivation of typhoid bacilli from the organs; (*b*) the use of the Widal test in large numbers of cases not clinically typhoid; (*c*) routine bacteriological examinations in large series of autopsies.

I find reports of 32 cases of typhoid fever in infants under two years of age, in which the diagnosis is proved by a positive Widal reaction (23), bacteriological examinations (5), or both (4).

Cassoute: Two months old. No fever. "Of all the usual signs of typhoid the only one present was persistent diarrhea." Death. Positive serum reaction in half an hour. Autopsy showed 14 infiltrated Peyer's patches, several of which had begun to ulcerate.

Griffith: Three months old. Diarrhea. No note as to roseola. Spleen enlarged. Duration fourteen days. Death. Positive Widal reaction from heart's blood. Autopsy showed throughout the ileum, and especially in its lower portion, Peyer's patches thickened, reddened and somewhat depressed. Microscopical examination showed infiltration and ulceration. The spleen was unusually large, soft and dark and the mesenteric glands enlarged.

Legry: Four months old. Bloody stools. Death. Autopsy showed enlargement of the follicles of the small intestine. Some isolated follicles and some of the Peyer's patches showed in their centers a depression corresponding to an ulceration to which was sometimes adherent a clot. Spleen enlarged. Typhoid bacilli cultivated from intestine and feces.

Roemheld: Seven months old. House epidemic. Abdomen slightly distended. Slight diarrhea. No roseola. No demonstrable enlargement of spleen. Duration, eighteen days. Death. Autopsy showed intestines normal except for slight injection of lowest Peyer's patches; spleen enlarged; mesenteric glands slightly enlarged; typhoid bacilli found in spleen.

Abt: Eight months old. Sudden onset with fever and vomiting. Fever high. Distention. Roseola. Spleen enlarged. Death with multiple gangrene. Positive Widal reaction. Bacilli "probably typhoid" cultivated from spleen.

Love: Eight months old. Dry tongue. No distention. No diarrhea. Roseola. No note as to spleen. Duration, twenty-one days. Recovery. Widal reaction positive.

Netter: Eight months old. Duration, nine days. Death. Widal reaction not mentioned. Autopsy showed lesions as well marked as in the adult. Cultures of typhoid bacilli obtained from spleen and mesenteric glands.

Netter: Eight months old. Duration, sixteen days. Death. Widal reaction not mentioned. Autopsy showed lesions as well marked as in the adult. Cultures of typhoid bacilli obtained from spleen and mesenteric glands.

Churchill: Eight months old. No note as to distention. Constipation. No roseola. Spleen not enlarged. Recovery. Positive Widal reaction.

Northrup: Nine months old. Stupor. Distention. Diarrhea. Roseola. Spleen enlarged. Duration, twenty-four days. Recovery. Widal reaction positive.

Méry: Nine months old. Breast and other food. No note as to whether nurse had previously had typhoid. No note as to distention, diarrhea or spleen. Roseola. Duration over two weeks. Recovery. Widal reaction positive.

Nobécourt and Berthrand: Eleven months old. Throat slightly red. Tongue coated in center, red at edges. Stupid. Strabismus. Rigidity of neck. Coarse râles both lungs. Meningeal symptoms marked at first and later diminished. Distention. Diarrhea. Roseola. Spleen not noted. Duration, over eleven days. Death. Positive Widal reaction.

Nobécourt: Eleven months old. No note as to distention or size of spleen. Rose spots and diarrhea. Duration and result not stated. Widal positive in dilution of 1 to 30.

Mitchell: Thirteen months old. Onset with fever. Bronchial and intestinal catarrh. Tongue coated. Distention. No note as to diarrhea or roseola. Spleen enlarged to percussion, but not palpable. Duration, eighteen days. Recovery. Positive Widal reaction.

Morse: Thirteen months old. Fed on milk. Mother had typhoid. Condition not typhoidal. No distention. Slight diarrhea. Roseola. Spleen easily palpable, two fingers' breadth below costal border. Duration, three weeks. Recovery. Positive serum reaction on three occasions.

Blackader: Thirteen months old. Slow onset. Seven days after onset picture that of incipient meningitis. Slight distention. Diarrhea. No roseola. Spleen palpable. Duration, twelve days. Death. Autopsy showed typhoid lesions and typhoid bacilli in the intestines.

Lazarus-Barlow: Thirteen months old. House epidemic. Bronchitis. Distention. Diarrhea. Roseola. Spleen not palpable. Duration, twenty-five days. Death. Positive Widal reaction. Autopsy showed normal intestines and a firm and somewhat enlarged spleen. Typhoid bacilli were isolated from the spleen.

Nobécourt and Berthrand: Fifteen months old. Tongue coated. Distention. Diarrhea. Roseola. No note as to spleen. Duration more than twenty days. Recovery. Positive Widal reaction.

Griffith: Fifteen months old. House epidemic. Distention not noted. Diarrhea. Roseola. Spleen not enlarged. Duration, three weeks. Recovery. Positive Widal reaction.

Samuels: Eighteen months old. Carphologia. Subsultus. 35,000 leucocytes. Distention not noted. Constipation. No roseola. Spleen enlarged. Duration, twenty days. Recovery. Positive Widal reaction.

Long Island College Hospital: Eighteen months old. Mother and sister had typhoid. Condition slightly typhoidal. No note as to distention or diarrhea. Roseola. Spleen enlarged. Duration, twenty days. Recovery. Positive Widal reaction.

Haushalter: Eighteen months old. Sudden onset with vomiting, diarrhea and stupor. Rigidity of neck; nystagmus; contractures; carphologia. Distention. No diarrhea. Roseola. Spleen not noted. Duration, fourteen days. Death. Positive Widal reaction. Autopsy showed the characteristic lesions of typhoid about the cecum but less intense than in the adult. Typhoid bacilli cultivated from the spleen.

Nobécourt: Eighteen months old. Distention, rose spots, diarrhea and splenic enlargement. Duration, thirty-eight days. Death. Widal reaction positive in dilution of 1 to 30. No autopsy.

Strasser: Nineteen months old. Acute onset with pulmonary symptoms and solidification of lung. No note as to distention. Bowels normal. Roseola. No note as to spleen. Duration, more than eighteen days. Recovery. Positive Widal reaction.

Griffith: Nineteen months old. Diarrhea. Roseola. Spleen much enlarged. Duration, four weeks. Recovery. Positive serum reaction.

Griffith: Nineteen months. Diarrhea. Roseola. Spleen much enlarged. Duration, not determined because of complicating diphtheria. Recovery. Positive Widal reaction.

Churchill: Twenty months old. No note as to distention. Diarrhea. No roseola. No enlargement of spleen. Duration not given. Death. Positive Widal reaction.

Bryant: Twenty-one months old. House epidemic. Distention. Diarrhea. Vomiting. No note as to roseola. Spleen enlarged. Duration, twenty-two days. Death. Positive Widal reaction in 1 to 20 dilution in two minutes. Autopsy showed intestines normal; spleen slightly enlarged; mesenteric glands large and soft. Cultures of typhoid bacilli which answered all tests were obtained from the mesenteric glands.

Churchill: Twenty-one months old. No note as to distention. Diarrhea. No note as to roseola or spleen. Recovery. Positive Widal reaction. Duration not given.

Nachod: Twenty-two months old. House epidemic. Diarrhea. Spleen enlarged. No note as to distention or roseola. Signs of bronchopneumonia. Duration not determined. Death from bronchopneumonia. Pronounced positive Widal reaction. Autopsy showed intestines normal. Peyer's patches not swollen and showed no loss of substance. The spleen was much enlarged. Mesenteric glands somewhat enlarged and rather hard. Cultures from the intestinal contents showed no typhoid bacilli. Pneumonia in right lung. He considers that the patient was recovered from the typhoid and died as the result of the sequelæ. On this ground explains the absence of the bacilli in the intestine and the presence of the Widal reaction.

Abt: Twenty-three months old. Distention, condition of bowels and roseola not noted. Spleen enlarged. Duration, sixteen days. Recovery. Positive Widal reaction.

Sixteen of these cases died and 15 recovered, giving a mortality of over 50 per cent. This figure is undoubtedly higher than the average mortality of infantile typhoid, because of the basis on which the cases were chosen. It does show, however, that typhoid is not a very mild disease in infancy. The spleen was enlarged clinically in 15, or 68 per cent. of the 22 cases in which it was mentioned. Rose spots were present in 16, or 69 per cent. of the 23 cases in which they were sought. Distention of the abdomen was noted in 11, or 73 per cent., of 15 cases. The stools were normal in one of the 27 cases in which their character is mentioned. There was diarrhea in 19, or 78 per cent., and constipation in 5, or 19 per cent. The average duration in 10 cases which recovered was twenty-one days, and in 10 which died, eighteen days. The fever was, as a rule, high. The onset was sudden in three cases; in one with vomiting, and in the others with pulmonary symptoms. Nervous symptoms were marked in four, in two of which meningitis was suspected.

Analysis of these cases seems to show that with some minor exceptions the symptoms of typhoid fever in infancy are essentially the same as in adults, but that the course is shorter and the mortality much larger. The conclusion seems justified that the type of typhoid in infancy, at least as regards its symptomatology and diagnosis, is the same as in adult life. It seems probable, therefore, that the reported cases afford a fairly reliable basis on which to determine the frequency of typhoid fever in infancy.

These conclusions must be accepted as essentially correct, if the cases on which they are based are representative. It is possible, however, that they comprise only the severe and fatal cases, and that many other milder cases have been passed unrecognized. If so, they are misleading. The two other methods for determining the type of typhoid in infancy, namely, the use of the Widal test in large series of cases not clinically typhoid, and routine bacteriological examinations in large numbers of autopsies, should settle this point. I know of but two comparatively small series of cases in which the former method, and of none in which the latter has been used.

Dr. Thayer and I, in 1898, tried the Widal test in 50 cases of gastro-enteric diseases in infancy. A positive reaction was obtained in but one case, and in this instance the agglutinative reaction may possibly have been transmitted from the mother. Our results were, therefore, essentially negative. Dr. Churchill, of Chicago, had the blood of 65 infants suffering from diarrheal diseases tested for the Widal reaction last summer. A positive reaction was obtained in four. Two of these died. Unfortunately, the cases were not carefully followed, and the rather meagre data teach us little or nothing as to the type of the disease in infancy.

Although the results thus far obtained from this method of investigation have been unimportant and inconclusive, it certainly seems to offer the most favorable means for determining the type of infantile typhoid, and indirectly the frequency of its occurrence. It must, however, be carried out in large series of cases, preferably in times of epidemic or in cities in which typhoid is prevalent. We cannot hope to get much help from such healthy cities as Boston and New York, but must look to such unsanitary places

as Philadelphia and Chicago for the solution of the problem.

*Conclusions.*—Typhoid fever occurs in infancy. Except for the lessened exposure in the first year through food, there is no apparent reason why typhoid should be less common in infancy than in later life; in fact, because of the greater susceptibility of infants to bacterial infection, it should be more common. Nevertheless, judging from the number of cases reported it does occur less frequently. This infrequency may be real or apparent. If apparent, it must be because the disease is unrecognized or mistaken for other conditions. Analysis of the reported cases, in which the diagnosis rests on a positive Widal reaction or positive cultures of the typhoid bacillus, shows that the type of typhoid fever in infancy, at any rate as regards its symptomatology, is essentially the same as in adult life. It is possible that this conclusion may be erroneous, as it may be based on the severe cases alone, the milder having escaped notice. The Widal test in large series of cases not clinically typhoid, and bacteriological examinations in large series of autopsies, offer the best means of solving this problem. The results thus far obtained by these methods are unimportant and inconclusive. They should be continued in large numbers of cases, especially in epidemics and in cities where typhoid is prevalent. In the light of our present knowledge, the symptomatology of typhoid fever in infancy is essentially the same as in adult life, and it is really and not apparently infrequent at this age.

## SOME CASES OF PROSTATECTOMY, OBSERVED AFTER AN INTERVAL.*

BY ALEXANDER B. JOHNSON, M.D.,
OF NEW YORK.

The condition of our patients upon whom we have operated, observed after a considerable interval, is always interesting.

The utility of certain operations is sometimes questioned, especially by our purely medical brethren, on the ground that we record our cases as cured because they are alive and able to walk out of the hospital. Without questioning the justice of this criticism in certain cases, it is always gratifying and instructive to learn that the improvement in health following a serious surgical procedure is satisfactory and permanent.

These remarks apply to cases of prostatectomy with especial force. In this condition the sufferings of the individual have been so great that permanent relief must be an inestimable boon. Upon pathological grounds, moreover, an interesting question arises, viz., we know that in advanced cases of prostatism at least, the condition depends not only upon the obstruction to urination produced mechanically by the enlarged gland, but also upon degenerative changes in the muscular structure of the bladder, and it might be assumed upon reasonable grounds that such changes would cause a permanent and perhaps progressive loss of expulsive power on the part of the bladder, resulting in insufficiency of even a progressive character and attended by a continuance of bacterial growth and cystitis.

Many of the cases also from whom the prostate has been removed suffer for a very considerable time from more or less complete loss of the sphincteric action of the muscles normally operating to prevent the leakage of the bladder contents—in other words they dribble. Whether this condition is ever a permanent one is a subordinate question of some interest.

The cases of prostatectomy in which I have been able to trace the later history of the individual are few, but I feel that, owing to the comparatively short time since this operation came to be generally performed, their presentation

* Read before the Section on Genito-urinary Surgery, Academy of Medicine.

needs no apology. I trust that this paper may call forth from the members of the society a relation of their own experiences in regard to the ultimate results of prostatectomy.

The cases of prostatectomy which I have done were operated upon by a perineal incision. A second abdominal incision having been used to afford access to the prevesical space, the fingers of the left hand inserted into this abdominal wound afforded counter-pressure for the fingers of the right hand working in the perineum. This method was first used by me on October 3, 1899.

It had been suggested by Dr. Parker Syms that an opening should be made into the peritoneal cavity above the pubes for the purpose of introducing the fingers of the left hand and pressing the prostate downward toward the perineum. It occurred to me that an incision into the prevesical space would be equally efficacious and perhaps less dangerous. It was, of course, the intention of Dr. Syms to sew up the peritoneal wound after the enucleation was completed, and it seemed to me that a defilement of the fingers of the left hand would be pretty sure to occur during the operation, with possible danger of infecting the peritoneum, and that perhaps an infection of the prevesical space might be less dangerous. Be that as it may, my first prostatectomy was operated upon in this manner. I sought to avoid infection of the suprapubic wound by making this part of the operation with gloves. The glove was then removed from the right hand and the perineal operation was performed. After draining and packing the perineal wound a fresh pair of gloves was put on and the suprapubic wound was sutured. Primary union of this portion of the wound occurred. At the time I attached no particular consequence to this trifling modification of the operative technic, and I have always been ready to agree that in a considerable number of cases the suprapubic incision opening into the bladder offers advantages in certain directions. I believe, however, that the suprapubic incision of the bladder itself is not always necessary or even desirable, and that primary union of the suprapubic wound, if such be made at all, can best be obtained by an incision into the prevesical space which does not open into the bladder.

I am aware that in slender, thin individuals perineal prostatectomy can be performed quite well without any suprapubic incision at all or by the use of some device for drawing down the prostate into the perineum, such as the water-bag of Dr. Syms, or by means of a hook introduced into the prostate through the rectum, as suggested by Dr. Gibson.

At the time I showed my first case of prostatectomy, on January 24, 1900, at a meeting of the New York Surgical Society, I was unaware that the incision into the prevesical space without opening the bladder had been used by anyone else. I subsequently learned that Dr. J. P. Bryson, of St. Louis, performed an operation in the same manner, at least as early as December 5, 1898.

According to the St. Louis *Medical Review* this modification was first suggested by Dr. Bryson in the issue of that journal of April 1, 1899.

A similar technic has been developed by Dr. Guiteras, published in the Philadelphia *Medical Journal*, April 20, 1901. Any small credit, then, which may belong to the originator of this modification of technic undoubtedly belongs to Bryson.

The perineal incision which I have used is the curved incision convex forward, extending across the perineum about on the level with the bulbous portion of the urethra.

After separating the muscles surrounding the urethra from the anterior extremity of the sphincter ani, the prostate is exposed by blunt dissection. A sound in the urethra affords a convenient guide during this part of the operation. When the prostate is reached it is pushed downward by the fingers of the left hand, inserted into the suprapubic wound, and it is usually possible in uncomplicated cases and with suitable retraction to expose the lower or perineal surface of the prostate to the eye. An incision is then made obliquely upward and outward through the capsule of each lateral lobe of the gland. The enucleation is then accomplished by separating the capsule of the gland with the forefinger of the right hand.

The most adherent surface is that in contact with the floor of the urethra, and a tear at this point usually occurs in separating one or the other lateral lobe. Through this opening the drainage tube is subsequently introduced into the bladder.

During the enucleation the downward pressure of the forefinger of the left hand is of the utmost practical utility for two reasons. The first reason is self-evident, viz., a point of counter-pressure is thus constantly maintained against which the enucleating finger is working. The second reason has not, I believe, attracted the attention it merits. It is that by the downward pressure the prostatic plexus of veins is put upon the stretch and their lumina obliterated. While the pressure is exerted the hemorrhage during the enucleation is at a minimum. When the pressure ceases profuse venous oozing occurs. Every ounce of blood lost by an old man diminishes his chances of a rapid return of strength and prolongs his confinement to bed, so undesirable in these elderly patients.

After the enucleation is completed the finger of the right hand may be introduced into the rent in the prostatic urethra and the bladder explored bimanually for stone or other complications.

While in the majority of instances a suprapubic opening into the bladder may not add materially to the immediate risks of the operation it does not appear to me in the average case to possess material advantages. If it be asserted that a suprapubic opening provides better drainage, it may be said in reply that perineal drain-

age is, in the experience of many, entirely satisfactory.

Moreover, it is hard for me to believe that the almost inevitable soiling of the suprapubic wound with infectious urine is to be regarded as an entirely innocuous condition. Indeed, in a case recently operated upon by me for the removal of the prostate, a former suprapubic operation for stone, done by another surgeon, was followed by urinary infiltration of the abdominal wall putting the patient's life in jeopardy and involving a slow and tedious convalescence.

There can be no question but that perineal drainage is less difficult to take care of, and if suprapubic drainage is imperfect, the abdominal wall is macerated in ammoniacal urine, rendering the patient a disgusting object to himself and others.

Although my cases have been too small in number to base upon the results any general conclusions yet, as far as they go, they would indicate that in individuals operated upon before the muscular tone of the bladder and replacement of the muscular bundles by connected tissue have advanced to a marked degree, there is no special tendency for the loss of power to expel the urine to become progressive; or, if such tendency exists, it is but slight. A résumé of the four cases observed after an interval substantiates this view:

*Case I.*—Aged sixty-one years; prostatectomy Oct. 2, 1899. Symptoms of prostatism had existed for five years; residual urine, 5 ounces. Jan. 24, 1900, residual urine, 1 dram—no cystitis; Jan. 2, 1903, residual urine, 1 ounce—no cystitis.

*Case II.*—Aged fifty-eight years; prostatectomy Feb. 15, 1901. Symptoms of prostatism had existed for four years; marked cystitis; absolute retention for four months. Examination three months after his discharge from the hospital, no cystitis; no residual urine. Examination Jan. 10, 1903, normal frequency of urination. A few shreds in the urine; residual urine not sufficient to flow through the catheter—estimated at one dram.

*Case III.*—Aged fifty-seven years; first attack of retention a few weeks before admission. Since then complete retention with dribbling. Bladder enormously distended. Prostatectomy July 18, 1901. Forty-five days later, urine normal; amount of residual urine too small to be measured. Examined Jan. 2, 1903, normal frequency of urination. Urine contains a faint mucous cloud; residual urine, 1½ ounces.

*Case IV.*—Aged sixty-four years; history of prostatism extending over nine years; severe cystitis; residual urine, 1 pint. Prostatectomy August 17, 1902. Fifty-six days later amount of residual urine very small. Cystitis cured. Five months later urination was said to be of about normal frequency. Urine for most part entirely clear. His residence is in another State, and his amount of residual urine I have been unable to obtain.

In order to illustrate the method *of removing the prostate which I have pursued* in these and other cases, I will read the history of Case III:

Prostatectomy. H. E. K., aged fifty-seven years. Merchant, native of Germany. Was admitted to the hospital July 14, 1901, complaining of retention of urine, with dribbling. The patient is a large, stout man, obese and rather flabby. He has a marked alcoholic habit. Has in general enjoyed good health and has never had any derangement of the genito-urinary tract, except gonorrhea, forty years ago. He has had retention of urine with dribbling for the past ten days, and has been catheterized twice during this time. The urinary bladder forms a large tumor reaching to the umbilicus. Sixty-four ounces of urine were withdrawn through a catheter and replaced by a pint of warm boric acid solution. While the bladder was empty, rectal examination showed a marked enlargement of the prostate. The urethra was found to be free from stricture. During the next few days the patient's inability to urinate continued. He suffered from an enormous polyuria. His urine was of low specific gravity, contained albumin and a few blood cells. Prostatectomy was proposed and done four days after his admission to the hospital. Gas and ether anesthesia. A two-inch vertical median suprapubic incision was made in the median line of the abdomen into the prevesical space. The patient was then placed in the lithotomy position. A sound was then introduced into the urethra. A curvilinear perineal incision convex forward was made extending from ischial tuberosity to ischial tuberosity. Anteriorly in the median line this incision crossed the perineum at a point a little in front of the tendenous raphé between the muscles surrounding the bulbous portion of the urethra and the sphincter ani. The skin and fascia were divided in the line of incision and the muscles of the bulbous portion of the urethra exposed. The tendenous raphé between the muscles surrounding the urethra and the sphincter ani was cut with a scissors and the rectum was separated from the urethra by blunt dissection with the forefinger of the right hand until the prostate was exposed. Two fingers of the left hand were then introduced into the suprapubic wound and used to press the prostate downward into view. In order to accomplish this the urethra was drawn forward and the perineal flap backward by means of retractors. The capsule of the prostate was then incised upon either side of the median line obliquely upward and outward.

Enucleation of the prostate was accomplished by the forefinger of the right hand working within the capsule, the fingers of the left hand being used for counter-pressure. Before the enucleation was completed the mucous membrane of the prostatic urethra was torn to a moderate extent, the bleeding was controlled largely by continuous pressure downward with the fingers of the left hand. Drainage of the bladder by means of a large thick-walled catheter

passed into the perineal wound and through the rent in the prostatic urethra into the bladder. Sterile gauze packing introduced upon either side of the catheter into the cavities, left after the removal of the lateral lobes of the prostate. Partial suture of the perineal wound at either angle. Suture of the suprapubic wound with clean gloves. The post-operative treatment consisted in systematic irrigations of the bladder with boric acid solutions, and the administration of urotropine by mouth. Perineal tube removed on the tenth day. Thirty-four French sound passed through the urethra into the bladder once every five days thereafter. Patient up on the twentieth day. No notable disturbance of temperature or pulse occurred.

Patient continued to leak through the perineum for six weeks, after which all the water was passed through the urethra. There was no cystitis. Amount of residual urine at the time he left the hospital was not noted. It is said to be small. This patient was examined Jan. 2, 1903. His general health, he states, is perfect. This coincides with his appearance. He says there are no symptoms to attract his attention to his urinary apparatus. He urinates at intervals from four to five hours during the day without effort and without pain. Only occasionally when he drinks beer is he obliged to rise at night. His urine shows only a faint cloud of mucus. The residual urine measures 1½ ounces.

*Case I.*—R. M., aged sixty-one years; entered the hospital Oct. 2, 1899. He gave a history of difficult urination with occasional attacks of retention extending over a period of five years. The patient was a small man, fairly well nourished. Examination showed a moderate symmetrical enlargement of the prostate. His urine showed the presence of well-marked cystitis. Residual urine five ounces. The patient was obliged to pass water every few minutes by day and at frequent intervals during the night. He suffered continual pain and was anxious to submit to a radical operation. Casts were not detected in the urine. Operation on the second day after admission. Suprapubic incision into the prevesical space. Curved incision in the perineum as described. Enucleation of the prostate. Suture of suprapubic wound. Perineal drainage. Primary union of suprapubic wound. Perineal drain removed on the tenth day. Stay in bed eighteen days. Leakage through the perineum for several weeks longer.

This patient was examined Jan. 24, 1900. At that time he had one dram of residual urine. He urinated with about normal frequency. His urine was clear. He suffered little or no pain. Examined again Jan. 2, 1903, three years and three months after operation. General health good. Urination every three hours during the day. Urinates once during the night. Urine absolutely clear. Occasionally at the end of urination he has a little twinge of pain as the prostatic urethra is closed. Has not had sexual intercourse since the operation, although he has desire and occasional erections. He believes that these are not complete. Residual urine, one ounce. He takes urotropine from time to time.

*Case II.*—S. B., aged fifty-eight years. Admitted to the hospital Feb. 11, 1901. No venereal disease. Patient is rather poorly nourished. Always well, except for bladder trouble, which commenced four years ago. Since then gradually increasing difficulty in urination. Four months ago retention. Occasional catheterization since that time. For the past fortnight retention has been complete. Moderate enlargement of the prostate to be made out per rectum. The left lateral lobe feels twice the size of the right. Urine withdrawn through catheter shows moderate cystitis with acid urine and a few granular casts. The patient was put upon urotropin and his bladder was irrigated with boric acid every eight hours for four days. Twenty-four hours' quantity of urine, 50 ounces. Prostatectomy Feb. 15, 1901. Two-inch vertical cut in the median line above the pubes opening the prevesical space; curved perineal incision as described. Exposure of the prostate. Prostate easily pushed into view with fingers of left hand introduced into the suprapubic wound. Incision of the capsule of the prostate on either side of the urethra and enucleation with the forefinger of the right hand. Perineal drainage with large rubber tube and packing. Suprapubic wound closed. Moderate hemorrhage during and moderate shock after the operation. Bladder irrigated daily through perineal tube. Perineal tube removed on the tenth day. Patient sat up on twelfth day. Thirty French sound passed every four days afterward, for sixteen days. Patient left hospital on thirty-ninth day. In this case the bladder ceased to leak through the perineum at an early date, and at the time the patient left the hospital the functions of the bladder had become nearly normal. The prostate seemed to contain rather more glandular tissue than usual. Its removal was very easy.

The patient was seen after an interval of three months. At this time he urinated with normal frequency and good force. There was no residual urine. His urine was entirely clear and free from pus. He had gained 25 pounds in weight. Examination Jan. 10, 1903. General condition excellent. Urination painless. Urinates three times during the day. Rises once to urinate at night. Urine, clear, contains a few shreds. Residual, one dram not enough to flow through catheter. Does not have erections.

Case III was described in a preceding column of this article.

*Case IV.*—G. H., aged sixty-four years. History of difficult urination extending over nine years. For the past two years his condition has grown much worse. Pain has increased, cystitis at times has been severe. For some time past he has had involuntary dribbling at night. The patient is spare in physique. He has moderate arterial sclerosis. The prostate feels uniformly enlarged. Residual urine, one pint. The urine

is alkaline. Specific gravity 1.010, contains albumin, blood and pus but no casts. He was operated upon Aug. 17, 1902. Prostatectomy was done easily by the operation already described. There was very little bleeding and no notable shock. The perineal tube removed on the seventh day but reinserted on the twelfth day on account of rise in temperature. Removed permanently on the twentieth day. Patient up on the twenty-first day. Daily irrigations of the bladder with boric acid alternating with permanganate of potash solutions. Urine first passed per urethram on the twenty-first day. Thirty-one French sound introduced through the urethra into the bladder once a week. Fifty-sixth day all urine passed through urethra. Upon leaving the hospital this patient had gained in weight and strength. The pain and discomfort connected with his urinary apparatus had disappeared. His urine contained only a few pus cells. Four months after operation patient states that his general health is fair. Urination is performed with comfort. His urine is for the most part clear. It is passed with a frequency only slightly greater than normal. Patient lives in another state, hence the amount of residual urine cannot be determined.

On Feb. 24, 1903, this patient reports himself greatly improved in general health. He states that as far as his urinary organs are concerned he is conscious of no discomfort whatever.

In all the cases observed after an interval sexual desire has been absent or notably diminished. Erections have either been absent or feeble.

## CASE OF BOTHRIOCEPHALUS LATUS IN A WOMAN IMMIGRANT, WITH REMARKS ON THE OCCURRENCE OF THIS PARASITE IN AMERICA.*

BY WILLIAM N. BERKELEY, A.B., M.D.,
OF NEW YORK.

Mrs. Weiss, born in Russia, female, forty-six years old, married, with several children. She applied at the Good Samaritan Dispensary in November last for treatment for a tapeworm. She had been in this country a few years. Had been passing segments of worm for years before her arrival (eight years in all, to her own knowledge), but had been so little inconvenienced that, to use her own words, "she thought she would wait to be treated till her children were grown and she had more time." She looked well-fed and plethoric, and complained only of vague digestive discomfort.

Oleoresin of male fern, preceded by the usual regimen, promptly expelled the worm complete.

I have been able to find no authentic notices in medical literature of a case of *Bothriocephalus* unquestionably of endemic origin in the United States or Canada, though it is said (authority not perfectly satisfactory) to be common in Mexico. George Dock (American System of Practice of Medicine) has observed three cases, two in Texas and one in Colorado, all imported. He knows of no endemic cases. Osler's account is to the same effect. Max Braun, in the last edition (1902) of his Thiersche Parasiten mentions a single case, reported from Philadelphia (without reference to the authority quoted or statement whether or not the case was imported).

I have observed in the last three years three other cases of *Bothriocephalus* (or *Dibothriocephalus*, as Braun writes it, returning to the original name), all among the same class of Russian immigrants. All of these patients enjoyed comparatively good health, with no special evidences of anemia, and no symptoms other than indefinite distress in the belly. One, a girl of nine years, had been brought by her parents to this country three years previously. The parents were positive that she had never passed tapeworm proglottides till three months before I saw her. I believed at first that I had discovered a true endemic case, but afterward concluded that the mother was too ignorant to serve as a credible witness. This case has therefore been classified with the others.

*Note.*—Dr. James Ewing mentioned in the discussion that he had reported to the New York Pathological Society some years ago an imported case of three worms in one patient, a Swede. Dr. Theodore Janeway also mentioned a case recently in his own care, imported, in which there were no signs of anemia.

40 East Fifty-eighth St.

* Reported to the New York Pathological Society, Jan., 1903.

## HERNIA.*

BY S. W. S. TOMS, PH.G., M.D.,
OF NYACK-ON-HUDSON, N. Y.
INSTRUCTOR IN SURGERY N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON, NYACK HOSPITAL; FELLOW, NEW YORK ACADEMY OF MEDICINE, ETC

Hernia, being synonymous with Rupture, is applied in general terms to the escape of any viscus through a congenital or pathological opening from the abdominal cavity where it is naturally contained.

Some herniæ are rare and will not be considered in this paper. Only inguinal, femoral and umbilical herniæ are under discussion because of their pathological importance, the frequency of occurrence and amenability to treatment.

The inguinal herniæ are of two varieties, oblique and direct.

The oblique or external may be congenital or acquired, and due to a predisposing weakness or imperfection in the tissues comprising the inguinal canal, *i.e.*, such as the non-closure of the vaginal process of the peritoneum following the prenatal descent of the testicle, and such herniæ are a frequent accompaniment of cryptorchism; another cause being the possible adhesion of a viscus to the peritoneal covering of the testicle

* Read at the Annual Meeting of Rockland County Medical Association, Nyack, Jan. 21, 1903.

within the abdomen, the descent of which causes a hernia to be drawn down with it.—(Sultan "Abdominal Hernias," Ed. by Coley.)

There are a number of anatomic peculiarities of congenital inguinal hernia, recently described by Bayer, which I need not enter into here (*loc. cit.*).

The acquired oblique hernia always follows the course of the inguinal canal with the spermatic cord and its vessels, and may stop at any point in its descent. When it does not appear at the external orifice it is termed incomplete and called a bubonocele. If, however, it passes through the external ring, it becomes *complete* and usually descends into the scrotum.

The fine anatomic distinctions of herniæ serve but to confuse and need not occupy our attention as they possess no particular consideration of a practical bearing upon treatment.

The direct or internal inguinal hernia protrudes directly through the internal inguinal fossa, being the space at the outer side of the rectus, which has no muscular covering, so that, in advancing years and relaxation of the abdominal parietes, a hernia bringing a portion of the relaxed abdominal wall before it can easily protrude at the external abdominal ring.

There is no preexisting canal here, hence this variety of hernia is never congenital and occurs only in adult or advanced life, being usually acquired as a result of chronic bronchitis or some other cause increasing intra-abdominal pressure. They are globular in shape, frequently bilateral, and seldom scrotal.

*The Importance of Hernia.*—The inguinal and femoral are the most common types, and their frequency depends upon sex, age, occupation and locality. Without going into elaborate and detailed statistics quoted by various authorities, the ratio of ruptured persons is about 1 to 15 in men and 1 to 40 in women (Agnew). More recent European statistics give 4.4 per cent., ranging from 19.6 per cent. in the first year to 1.14 per cent. in the fifteenth year. (Berger.) As this affliction is responsible for the lessening of the earning power of the individual by 10 per cent., with a reducible hernia perfectly retained, it can be somewhat appreciated what the large number of affected cases means in the unequal struggle for maintenance, to the sufferer and his family, and to the industrial economy of the State; and correspondingly greater if the hernia is retained with difficulty, is irreducible or of large dimensions. (Sultan.)

*Etiology.*—Predisposing factors are seldom if ever wanting, such as anatomical weakness and defects of a congenital nature. Malformations, as a subperitoneal lipoma acting as a wedge and making traction on the peritoneum, producing a true hernial sac. An ectopic testis is usually accompanied by a hernia. Other causes I have previously referred to.

Heredity is certainly a remarkable element and frequently observed in the hospital clinics, where several members of the same family are subjects of hernia.

Chief of the exciting causes is increase of intra-abdominal tension, coupled with a congenital predisposition; straining at stool, sneezing, lifting, blowing wind instruments, logging, long and exhaustive marches, tight belts, *especially in infancy;* the sitting posture, favoring weakening of the abdominal muscles. Phimosis in infants causing reflex irritation of the vesicle neck in straining to micturate. The development of the hernial sac is favored by rapid emaciation, and also by the accumulation of fat, and excessive length of mesentery. Traumatic herniæ are infrequent because there must have already existed a congenital sac.

*Symptoms.*—Many cases of acquired hernia, of the inguinal oblique and femoral varieties, are unable to give a definite history of onset, while others can define the sensations occurring subjectively when the hernia is produced by some physical exertion. There is usually a feeling of something having suddenly given way, a stinging or burning sensation in the locality, while the pain may be referred to some distant part, as for instance to the umbilical region. There may be nausea and a feeling of faintness, followed rapidly by graver indications.

The objective symptoms may be wanting, but cases have been reported where a viscus has been protruded, and produced immediate strangulation.

All herniæ produce discomfort, with frequently more or less local and reflected pain and colic; dyspeptic symptoms; a sensation of weakness and insecurity upon exertion; difficulty in rising from sitting posture and maintaining an erect position; inability to endure enforced or prolonged fatigue; an altered sensation down the legs, due to the pressure of the hernia or a truss pad on the ilio-inguinal nerve; often a coldness; sometimes partial anesthesia; the bowels are frequently constipated and irregular; and pain is experienced at stool. Bladder symptoms usually exist in old and neglected cases; and the mental condition of the patient is often one of depression, introspection and self-consciousness. The symptoms of an irreducible or incarcerated hernia may be all those enumerated above and frequently exaggerated. In cases of strangulation all degrees of intestinal obstruction are present from those of a mild type (where only omentum may be strangulated) to the more profound, with shock, rapid pulse, subnormal temperature, vomiting, obstipation, and abdominal pain are present.

*Diagnosis.*—The first point in diagnosis of inguinal hernia in the male is to ascertain if the testicle and cord are in the scrotum. If in the inguinal canal, whether they can be brought down into the natural repository or reduced into the abdomen. If the latter, by invaginating the scrotum with the finger (or the loose tissue of the mons in the female), to ascertain whether the orifice is above or below Poupart's ligament. If

below, it is femoral; if above, an inguinal oblique. Should it be internal to the inguinal canal in an elderly person, with a history of acquiring it after middle life, in shape oblong or globular, and not scrotal, it belongs to the direct variety.

If a moderately sized hernia, located in the groin, what other affections may it be confounded with? If the tumor is in a male and reducible, it is most likely an inguinal hernia, as the hernial orifice can easily be determined, as indicated, in most subjects; yet in a very fat woman it is often difficult to determine whether the orifice is above or below Poupart's ligament.

Again, in very large scrotal herniæ, to which side does the hernia belong? When reducible the side to which the hernia can be made to return, and the location of the testicles will serve as reliable guides, as the testicle of the healthy side remains in the proper position, while the other is posterior and pushed downward.

Nearly all scrotal herniæ in infants and children appearing soon after birth are congenital.

An existing hernia, reduceable through the internal inguinal ring, the canal being empty at time of examination, can be diagnosed by a slight amount of abdominal fluid perceptible in the hernial sac, felt in the course of the canal, the patient being in the upright position.

In adults the increasing size of a hernia gradually dilates the inguinal canal and finally causes it to lose its oblique direction, often making it difficult to determine an oblique from a direct hernia. The latter usually stops at the root of the penis and rarely descends into the scrotum.

As an inguinal hernia can be mistaken for a retained or dislocated testis, swollen lymphatic glands, psoas abscess, a subperitoneal lipoma, cyst of the round ligament and frequently for a hydrocele of the cord, it is important to be able to differentiate these conditions.

We should commence with inspection by systematically examining the patient after a careful history and cross-questioning which will furnish subjective information. Does the tumor correspond to one of the hernial openings, and has it a pedicle attached within the abdomen? Does it change with the position of the patient, and is the impulse exaggerated by coughing? In palpating the tumor, does its base enter the orifice within the abdomen, or can it be separated by the thumb and finger?

Among the surest signs of hernia are its reducibility, tympanitic sound, and gurgling on manipulation when bowel is involved. If omentum, it has a doughy feel, lumpy, and reduction more difficult, with absence of gurgling. When incarcerated, the diagnosis is more difficult, yet the antecedent history of the case helps to confirm the diagnosis.

As all abdominal herniæ are subject to the same general laws it does not seem necessary to go into details regarding the recognition of the others, as anatomical landmarks serve to give them a name. The following are the main features of *inguinal hernia* and *hydrocele testis:*

| | |
|---|---|
| ANAMNESIS. | |
| "The tumor appears suddenly during an augmentation of the intra-abdominal pressure; or gradually, in which case the swelling is first noticed in the abdominal wall and the enlargement is toward the testicle. | The swelling develops more slowly, not rarely after a contusion of the scrotum or inflammatory changes in the epididymis.<br>The swelling commences in the bottom of the scrotum and gradually spreads toward the abdomen.<br>With a single exception (hydrocele communicans) they do not suddenly change in size. |
| INSPECTION. | |
| "The swelling seems to be directly continuous with the tissues of the abdomen.<br>"The swelling is not translucent; in rare cases, in very young children, it may be translucent. | The swelling is usually sharply circumscribed from the abdomen.<br>The swelling is translucent; if the walls are very thick, or if spermatic fluid or blood is present, it may not be translucent. |
| PALPATION. | |
| "If an attempt is made to draw the tumor away from the abdominal wall between the thumb and index finger, a portion of the tumor is felt passing into the abdominal cavity.<br>"The tumor may be replaced. | If the same attempt is made nothing is felt between the tumor and the abdominal wall but the constituents of the spermatic cord.<br>The volume of the tumor remains unchanged upon pressure (with the exception of a hydrocele communicans). |
| PERCUSSION. | |
| "Under certain circumstances, a tympanitic note is obtained."—(*loc. cit.*) | Always dull upon percussion. |

*Prognosis.*—The common forms of all abdominal herniæ tend to recovery by mechanical means during the first two years of infancy.

After the child is able to run about in the erect posture, mechanical treatment becomes less efficient and cures are the exception instead of the rule. There are many reasons for this. An active child rebels against the irksome restraint of even the best fitting truss; carelessness upon the part of parents, in their attentions, and often an improper appliance is worn.

Prognosis in the operated cases depends upon the conditions, the kind of hernia, age, etc.

Operations of election by the Bassini method in inguinal hernia are seldom failures, and a death in one to 300 to 500 is quite a high rate of mortality. Recurrences in femoral are occasionally seen. Umbilical will furnish the highest death-rate because of the class of subjects afflicted, corpulent, full habit, with poor heart and kidneys. The mortality in strangulated cases depends, like appendicitis, on the time of operation.

*Treatment, Mechanical and Surgical.*—The management of hernia to-day is tending more toward the radical than ever before, because of the safety of operation in a death-rate of infinitesimal proportions, the decreased likelihood of relapse since the newer methods have devised a secure operative procedure, and the short time spent in confinement to bed (being about ten days), the percentage of cures being one-hundred in those cases of primary union in healthy subjects.

Yet, no matter how much advance there may be in the art of surgery, the mechanical treatment of this affliction must always remain the chief source of relief to the vast majority of sufferers. The reasons for this are so obvious to us all when a patient consults us that to give them, to emphasize the statement recorded, would be superfluous.

To all infants with uncomplicated conditions the application of a properly selected and well-fitting truss, coupled with a reasonable intelligence of the mother or nurse, will effect a cure within a year or eighteen months in 90 per cent. of all cases, under safe-guarding observation by the medical attendant. This is because the inguinal and umbilical herniæ are most amenable to such treatment, and usually are the only varieties met with in this period of life.

Recumbency of the little patients prevents the hernia descending through the patulous orifice except in straining, when the pressure of a truss *over the ring* affords necessary protection. Recovery takes place not by any occlusion of the sac or by adhesive inflammation, as has been generally concluded, but by a true retraction of the sac within the abdomen.

I will not enter into the history of trusses, which is very interesting, as space does not permit, but state my reasons for the rejection of the ordinary forms on the market, and the ones usually sold by the dealer or selected by the wearer.

The German and English patterns are mostly used, and I cannot express my condemnation of them in sufficiently strong terms, because the pad, resting as it does on the pubic bone, allows the hernia to protrude through the internal inguinal ring, acting constantly as a dilating wedge in the whole course of the inguinal canal. Its prolonged use tends to enlarge the opening and eventually causes the internal ring to widen down into the external, until it becomes one immense aperture into the abdominal cavity. Therefore all possibility of a cure resulting spontaneously from a proper retention of the hernia is absolutely removed, and the condition made worse.

This objection applies to most of the different forms of continuous spring trusses where the pads are placed upon descending arms and exert the pressure in a direction that invariably enlarges the hernial openings and canal.

Sir Astley Cooper, in the early part of the last century, appreciated these defects. He stated: "The object in applying a truss is to close the mouth of the hernial sac, and destroy its communication with the abdomen, and this object can never be perfectly fulfilled by any truss which is applied upon the external abdominal ring."

"The essential requisites of a good truss," says Holmes (Syst. Surg.) "are these, that it should fit easily, should not shift by any movement of the patient's body, not gall the skin, or any part project against the abdominal wall; its pad should cover the hernial aperture and its pressure should be directed properly, and should be great enough to prevent the descent of the hernia in any position or exertion which the patient may make; but it should not be so severe as to cause enlargement of the opening; the pads should be supported with the least possible force or the application will become irksome. . . . Variations in pressure are very essential in order to adapt it to different circumstances; finally the direction in which the pressure is made must correspond to that of the inguinal canal."

The cross body or Marsh truss and the Hood pattern meet these requirements admirably. The former includes fully two-thirds of the body, and is applied from the opposite side; the points of pressure being over the internal inguinal ring and the gluteal muscles of the affected side by a counter-pressure pad on the distal end of the spring. When shaped to the individual form it is worn with comparative comfort and security. The pad and pressure should be suitable to the case under treatment. This truss is best suited for femoral hernia as well as inguinal oblique.

The Hood truss is an encircling spring with solid front, carrying one or two hernial pads, and open at the back, being fastened by a short connecting strap. The spring being of German silver is readily malleable, and when these trusses are covered with an impervious material they are cleanly and comfortable. This truss is so shaped that it passes about the pelvis at the most immovable point, and is, like the cross-body, entirely out of the way of the muscles of locomotion, allowing perfect freedom in all movements of the body.

These two forms of trusses are efficient, and combine security with ease of wearing when properly fitted, being suited to all ages and conditions that admit of a hernia being retained by mechanical means.

Belt trusses are only mentioned to condemn, as they constrict the hips, giving very little pressure over the inguinal region where it is most needed. They have a place as a night truss, when it becomes necessary to employ one where a persistent cough is present. That patients afflicted with hernia who consult the average physician are not advised and treated as other medical cases are is manifestly true, the usual advice being "Go to the druggist and get a truss." This vague prescription is chargeable, to say the least, to listlessness of physicians, who thereby forfeit a kind of professional service, through inability to apply mechanical therapeutics for which they could justly claim compensation. By proper forethought the profession could instead reserve to its own members a pro-

fessional duty which now goes by default to druggists, who are seldom more qualified, and should be considered less so than the physician, to perform it. Infinitely more satisfactory for both patient and physician would it be if professional selection and guidance were exercised for the sufferer's benefit in the proper adjustment of a suitable appliance. The whims and prejudices of patients, and their crude ideas formulated from the continual failures and discomforts of badly fitting trusses, as to what is needed for their cases, are seldom reliable guides in the selection of a suitable appliance.

In an address to the New York Medical Association meeting in 1889 Dr. Jos. D. Bryant said:

"The greater number of medical men of the present day are blissfully ignorant of the truss armamentarium now in the market, also of the measurement, means, and method of fitting them properly to patients. The patients thus afflicted are relegated to the 'instrument makers,' or to other mechanical agents for the proper (?) truss or appliance, and the application of it. In a large number of cases, no doubt, this course on the part of the medical man is actuated by the sense of his own inability to meet the demands of the case; when this is the true cause, while we may commend him for his sincerity, still we must respectfully submit that he is a much too willing exponent of the sentiment that teaches 'where ignorance is bliss 'tis folly to be wise.'"

Sir Astley Cooper gives these directions for fitting a truss: "Therefore, when a hernia has been returned by the surgeon into the abdomen he should lay his fingers obliquely above and to the iliac side of the ring and direct his patient to cough; and the farthest part from the ring toward the spine of the ilium, where the internal sac is felt to protrude is the point which should be noted for the application of pad of the truss and the instrument made accordingly."

*Fitting Trusses.*—I should not feel justified in occupying more of your time in speaking of trusses or enlarging my plea for a better understanding of the subject and the therapeutics of hernia generally, but will direct your attention to the practical side of the question of fitting them. I cannot do better than quote Prof. W. B. DeGarmo's rules for measurement and method of fitting, as given in a lecture delivered at the Post-Graduate Medical School: "After getting the measures, which should be taken by passing the tape-line around the pelvis, about two inches below the crest of the ilium, and over the internal ring, we should next secure the shape of the hips and place it upon paper, where it will be of real practical use in molding the spring for the patient. This is done by the aid of a strip of sheet-lead, half an inch wide and one-sixteenth of an inch thick, by about 20 inches long. I place this across the front of the abdomen with one end resting over the internal ring, we will say of the right side. The lead is now molded to the shape of the front of the abdomen, and around the left hip to the center of the back or a little beyond. Having been pressed to the exact shape of the surface of the body, it is now carefully slipped off from the left side and placed edgewise upon a sheet of paper of suitable size. Its inner surface is traced around by a lead-pencil, and the process is either repeated for the opposite side, or you may simply turn the lead over, thereby completing a tracing of the circumference of the pelvis.

You should now select the size and style of spring which you desire to use, and shape it to fit this tracing. If you select a cross-body spring, begin by shaping that portion which passes over the front of the abdomen to correspond to the diagram on the paper, and so follow around, of course allowing for compression. This method so far simplifies truss-fitting as to place it within the reach of every practitioner who is willing to devote the required time to the interest of his patient.

Springs covered with hard rubber must be warmed before bending. When you have supplied your patient with a good-fitting truss, you have not fulfilled your entire duty. The subsequent care of the case is of equal importance. I keep all children under care, having them come back at stated intervals until they are cured. Usually I see them not less than once a month. Do not allow the parents to decide whether attention is needed or not, but have them bring the child back, that errors may be corrected in the fitting of the truss which they would never see. Adults should be impressed with the importance of reporting three or four times every year, even after perfect fitting is secured, that you may decide whether they are wearing their trusses right, and that their hernias are being securely held in place.

In the care of the skin, to prevent excoriation, cleanliness is of the utmost importance. The truss as well as the person must be kept clean, and, as far as practicable, dry.

Before describing the surgical treatment of hernia, it might be considered in keeping with the scope of this paper to describe the methods best suited in using taxis for *recent* cases of strangulation.

Taxis, or restoration of the hernial viscus to the normal position by mechanical manipulation is termed reduction or taxis.

1. *Position.*—The body should be recumbent, the knees flexed, if necessary, or such attitude as to relax muscles of part. In femoral hernia the knee of affected side should be flexed obliquely, inclining to opposite side. In inguinal scrotal, place thumb and finger of left hand at the neck of tumor to prevent invagination of intestine and overlapping at orifice and guide its course through internal inguinal ring. Grasp body of hernia with right hand, draw carefully downward and outward, then gently compress tumor, equalizing pressure as much as possible, except that it should be greatest at bottom. Gurgling often manifests the fact that the hernia has re-

ceded.* Care should be taken not to reduce the testicle with the hernia, if adhesions connect the two together. The application of ice-bags, or hot fomentations of hops often assist in the taxis of recently strangulated hernia, also the hypodermic injection of atropine gr. $^1/_{25}$, into the constricted ring.

In femoral hernia the pressure on the hernial tumor must be made downward, to saphenous opening, and then upward. Long-continued and too often repeated efforts at reduction are frequently followed by inflammation, particularly so in this form of hernia.

The difficulty in exerting taxis on large umbilical herniæ in fat people is the tendency for the hernial viscus to slip between the fat and the skin or muscles; and in most of these cases the sac is adherent. Sometimes there is more than one opening, and this impression may be often formed from another condition of the "pocketing" of the hernia, to one side or other of the hernial orifice in the fascia or adipose tissue. Both hands should be used and placed around it, the manipulation being chiefly conducted by the thumbs and fingers in a rolling or kneading motion.

*Surgical Treatment.*—It is not my purpose to describe the various methods of operating for the relief and cure of hernia, as my paper is already too long. The great names in the history of surgery are attached to some personal technic for its treatment. The object formerly sought by a radical cure was the obliteration of the sac by some means; for it was firmly rooted as an established fact that this was the primary cause of hernia. The prejudices of the medical profession die hard, and it was not until Bassini, of Padua, read his paper before the Italian Congress of Surgeons in 1888, relating his 102 cases (seven of which were strangulated) without a failure and with no mortality, at the same time stating it was his belief that it was the anatomical defects in the inguinal canal and *not* the sac per se which were responsible for hernia; and in obliterating the canal as well as the sac lay the secret of radical cure, that this operation was accepted by the profession generally. Only about a month later Halstead, of Baltimore, published a new operation almost identical to that of Bassini, excepting that in his treatment the cord is external instead of below the sutured aponeurosis.

"Bassini aims, by his operation, to completely close the hernial canal within the abdominal wall, and to form a new canal for the cord which shall correspond as much as possible to physiological conditions. His radical operation is composed of three steps:

"First step: The pillars of the external abdominal ring and the aponeurosis of the external oblique muscles are exposed by an oblique incision corresponding to the course of the spermatic cord. The aponeurosis of the external oblique muscle is now incised up to a point above the location of the internal abdominal ring, separated from the underlying tissues, and the two flaps turned back to either side. The hernial sac is now separated from the spermatic cord by blunt dissection and completely isolated from the surrounding tissues, particularly in the vicinity of the neck of the sac, so that every trace of a funnel-like diverticulum disappears. After the hernial contents have been reduced, the sac is opened at some distance from the neck, and adhesions between the sac and contents separated, the protruding portions of omentum ligated in sections and extirpated, and the hernial sac ligated as high up as possible. The sac is then cut off one centimeter below the ligature and the stump is buried in the abdominal cavity.

"Second step: The isolated spermatic cord is lifted up and held to one side. The two flaps of the aponeurosis of the external oblique muscle are held back by retractors, and the whole mass of muscle situated internally—the larger upper portion, composed of the internal oblique and transversalis muscles, the smaller lower portion, composed of the rectus muscle—is united throughout its entire extent with Poupart's ligament by four or five mattrass sutures, so that only a sufficient opening for the spermatic cord is left in the upper and outer angle of the wound.

"Third step: The spermatic cord is laid upon the newly formed posterior wall of the inguinal canal, and the two flaps of the aponeurosis of the external oblique muscle are sutured over it, thus forming the anterior wall of the new inguinal canal.

"The operation is concluded by the suture of the cutaneous wound."*

The importance of the Bassini technic lies in closing the space or bed of the spermatic cord and vessels, and making a true posterior wall that formerly was deficient. All former operations omitted this important feature, which insures against relapses. It is a most remarkable fact to think that all the great surgeons of the past never fully appreciated wherein their operations were defective, and the security this one feature of the surgical procedure in curing hernia would give in preventing recurrences; lifting the considerations of prognosis from doubt and uncertainty to one of promise and future safety.

When dealing with an ectopic testicle where the short cord prevents its descent into the scrotum, a pocket can be made in the subperitoneal space posterior to the lower portion of the rectus, and the testicle placed there where it has the protection of the lower abdominal wall.

The after-care of these cases is ten days in bed, allowing them to return home in two weeks, the wearing of a snug abdominal band of Canton flannel with perineal straps for six weeks.

In operating on femoral herniæ, the incision is made over the tumor longitudinally, exposing the

* Article of W. H. Bennett, F.R.C.S., in Lancet, Aug. 20, 1892, "Dangers of Indiscriminate Attempts at Reduction of Strangulated Hernia by Manipulation."

* This concise description is given by Sultan.

hernial sac, reducing its contents, ligating it as high as possible, and excising it.

The closure of the ring is best accomplished by passing the sutures through Poupart's ligament, the pectineal fascia, and the periostum of horizontal ramus of the pubis.

*Umbilical Hernia.*—The tendency to this form of hernia in young children and infants to spontaneous cure when appropriately treated makes the surgical treatment rarely necessary. A gauze pad fastened by a strip of adhesive plaster encircling the abdomen and changed as required, usually effects a cure. The parts should receive proper antiseptic cleansing, the gauze sterile and some non-irritating and slightly antiseptic powder applied.

The surgical treatment is reserved to the strangulated, incarcerated, and large herniæ of adult life.

A marked advance was made by Gersuny, who suggested opening the sheaths of the recti, and uniting the internal borders of these muscles as well as the usual sutures of the hernial orifice. It is always well to perform omphalectomy and the overlapping of the muscles, as recommended by Blake, of New York, give the best results (*loc. cit.*)

*Report of Cases.—Case 2359.*—A. T., male, aged five years, right inguinal oblique. Duration since six weeks old. Operation at Post-Graduate Hospital, disclosing congenital sac. Bassini method. Primary union. Left hospital on fourteenth day.

*Case 2361.*—E. R., male. Right inguinal oblique scrotal hernia observed at fourth month. Ectopic testicle. Operation at Post-Graduate Hospital July 17. Bassini operation. Cord too short to allow of testicle being placed in scrotum. It was dealt with as described above. Primary union. Left hospital on fourteenth day.

*Case 2373.*—H. D., male, aged two years. Left inguinal oblique scrotal. Duration since birth. Size of small egg. Acute strangulation. Operation at Post-Graduate Hospital July 21. Primary union, leaving hospital on fourteenth day.

*Case 2375.*—I. M., female, aged twelve years. Double inguinal oblique. Duration ten years. Operation at Post-Graduate Hospital July 28. Primary union, leaving hospital on fourteenth day.

*Case 2382.*—L. McN., aged ten years. Right inguinal oblique. Contents omentum, congenital sac. Duration since infancy. Operation at Post-Graduate Hospital, August 19. Primary union, leaving hospital on fourteenth day.

Case (Private).—Geo. McK., aged thirteen years. Right inguinal oblique, congenital. Duration since infancy. Boy poorly nourished, weighing 84 pounds. Operation at patient's home, assisted by Dr. Maynard, on August 20. Some slight gaping of skin wound and sluggish healing, requiring confinement to bed for two weeks. This did not affect the result of operation and patient had a perfect recovery and rapidly put on flesh weighing 113 pounds in five months.

*Case 2400.*—D. H., male, aged twenty-eight years. Epigastric hernia in linea albi one inch above umbilicus. Duration, 3½ years. Content omentum. Operation September 23, at Post-Graduate Hospital. Closure of hernial openings (two) with Kangaroo tendon opening sheaths of recti and bringing edges of these muscles together over the sutured apertures. Primary union, patient leaving hospital on fourteenth day.

*Case 2404.*—L. P., female, aged thirty-three years. Right inguinal oblique. Duration four months, caused by coughing soon after a confinement. Operation at Post-Graduate Hospital, September 30. Primary union, leaving hospital on the fourteenth day.

I wish to acknowledge my indebtedness to the assistance I have derived from the writings of DeGarmo, Cooper, Heaton, Holmes, Agnew, Gross, Bryant, and Sultan, in the preparation of this paper. I have freely made use of quotations in some instances from these authors, full credit for which I wish to make herewith.

## THIOCOL.*

BY J. LEFFINGWELL HATCH, B.SC., M.D.,
OF NEW YORK;
FORMERLY LECTURER ON BACTERIOLOGY AND DEMONSTRATOR OF MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; PATHOLOGIST TO THE PHILADELPHIA HOSPITAL; LATE SANITARY INSPECTOR FOR THE PORT OF ANTWERP (BELGIUM), IN THE U. S. MARINE HOSPITAL SERVICE, ETC.

Ever since the efficacy of creosote was established in pulmonary affections, the medical profession have been striving to find a derivative of this coal-tar product which would be free from the unpleasant properties and effects of that drug. Both guaiacol and creosote act as irritants and even caustics on the mucous membrane of the entire alimentary tract. Besides this, they have an unpleasant odor and taste, on account of which the patient receives them with repugnance. They are both to all practical purposes insoluble in water, but are somewhat soluble in a 50-per-cent. solution of alcohol; however, such a solution is irritating in itself, owing to the alcohol, liability to excite coughing and leaving a sensation of burning in the throat which remains for some time after its ingestion. On account of these facts the different acid esters of guaiacol have been substituted, but while in some instances they are tasteless, yet they are all insoluble in water, and moreover are not broken up into their compounds in the stomach, but merely undergo a partial decomposition on reaching the alkaline intestinal secretions, consequently they are but a poor substitute.

More recent investigations into the synthetic chemistry of the diatomic phenols have given rise to a more successful compound of guaiacol that

* (Guaiacol—sulphonate of potassium Roche.) A soluble form of guaiacol, its uses and advantages over the insoluble derivatives of creosote, such as guaiacol, duatol, and other diatomic phenols.

is readily soluble in water, free from the taste and obnoxious odor of creosote, non-toxic, and extremely assimilable. This new preparation is called thiocol, the potassium salt of orthoguaiacol-sulphonic acid. The formula may be represented by $C_6H_3.OH.OCH_3.SO_3K$. It occurs as a white micro-crystalline, odorless, permanent powder, of a faint bitter-saline but not disagreeable taste. It is readily soluble in water and dissolves also in dilute alcohol, but it is insoluble in ether or in fatty oils. Its aqueous solution is colored blue by ferric chloride, the color changing to wine-yellow on the addition of ammonia water. Thiocol has a powerful reducing action on silver salts and ferric compounds, and at once decolorizes permanganate solution.

After the administration of thiocol, almost the total amount of sulphur from the medicament is found in the urine as sulphate, with a small proportion of guaiacol-sulphate.

The physiological action of creosote is purely as an antiseptic. It is an excellent preservative, for meat can be kept in it indefinitely. This feature, however, has always been a drawback to its exhibition in large quantities for any length of time, as it deranges the stomach and finally renders that organ unfit for work.

According to the physiological experiments made by Dr. G. Rosebach at the Medico-Chemico Institute connected with the High School at Berne, Switzerland, and by Prof. Jaquet at the Medical Clinic of the University of Basle, Switzerland, thiocol, when given per os or injected subcutaneously, is non-toxic, producing a striking increase in weight and showing no injurious effect upon the composition of the blood.

In most cases they found an increase in the number of blood corpuscles and the amount of hemoglobin; in others the quantity remained unchanged. Furthermore, the animal experiments proved the extreme assimilability of thiocol as against other guaiacol compounds—where only 7 per cent. of guaiacol was absorbed, 70 per cent of thiocol was assimilable.

The advantages of thiocol, then, over other guaiacol preparations are, after its tastelessness and freedom from unpleasant odor, its free solubility in water and permanence in the air which allows it to be dispensed as powder, tablet, or in solution; its high percentage of absorption and its non-toxicity when administered either by mouth or by hypodermic injection.

Having thus found a substitute for creosote which, besides having its antiseptic properties, is free from those objectionable features of the creosote itself, and moreover having additional advantages of its own, let us look at the pathologic conditions in which it is indicated, so that a clearer and more intelligent idea of why it produces certain effects may be obtained, and not give it simply on account of the old maxim "Post hoc, propter hoc."

As every pathologic lesion must be preceded by a change in function, we find that in the inflammatory diseases of the respiratory tract they are preceded by a hyperemia, this hyperemia usuall being induced by exposure to cold, or by irritating particles in the inspired air. The hyperemia is soon followed by a mucous exudate which is later augmented by leucocytes and red blood corpuscles, which, unless thrown off by coughing, form a nice nidus for the development of germs.

The process which, until this point has been limited to the mucous and submucous membrane of the bronchi and bronchioles, if not arrested proceeds by continuity of structure to the surrounding tissues (the parenchyma), and the inflammation becomes more intense; at the same time pressure from the accumulated products of inflammation so press upon the blood vessels that anemia now takes the place of hyperemia and degenerative changes occur, such as hepatization, yellow atrophy, caseation, etc.

Besides this, the toxins which are formed by the bacteria that gain entrance into this excellent culture medium and thrive there luxuriantly, affect profoundly the nervous system and also exhaust the valiant white blood corpuscles in their strenuous effort for supremacy.

This general picture covers the entire field of pathogenic changes from a simple acute bronchitis, through chronic bronchitis and pneumonia, up to pulmonary phthisis, the different forms of bronchitis depending only upon the severity and length of the attack; while the pneumonia and phthisis are due to their respective specific germs and the anatomy of the part affected.

Tuberculosis of the lung is probably the most exhausting of all diseases and the most difficult to arrest, because the bacillus, which forms the toxic ptomains that sap the patient's vitality, is surrounded by impregnable walls of connective tissue that shut off all approach from the blood current. However, it is not only the tubercle bacillus that is at work undermining the constitution, but the staphylococcus and streptococcus, which linger more superficially in the mucous membrane and around the walls of cavities, producing a septic condition that we call the mixed infection, and which is accountable for untoward results and neurasthenic conditions.

The first and most important feature, then, after the invasion, is the germ and this calls for an antiseptic; the pyrexia, night-sweats, nervous symptoms and pain, are due to the accumulation of the products of inflammation and toxins. These are at first prevented from further elaboration by arresting the process of inflammation and killing the germ that produces them; then such material as remains must be filtered out from the blood through the bowels and kidneys by means of purges and diuretics. The accumulations in the air-passages will be removed reflexly by coughing aided by stimulating expectorants, and the irritated mucous surfaces must be soothed and gently stimulated to produce their natural secretions, so that harmonious interchange between the air and blood can take place in the alveoli. After all these things have been accomplished the nervous system must be toned

up, the broken-down tissues rebuilt, and the exhausted leucocytes rejuvenated. When all of this has been accomplished, then, and not until then, is our patient cured. It will at once be seen that in thiocol Roche we have a remedy combining all the factors necessary for such results, in consequence of its non-irritativeness and non-toxicity it does not give rise to untoward symptoms of any kind, not even with continued use; owing to its great assimilability, it affords the possibility of successfully combating phthisis, causing such symptoms as emaciation, anorexia, decline of strength, fever, night-sweats, etc., to disappear in a short time, quicker than any other medicament hitherto used in phthisis, and the clinical testimony of authorities, both in Europe as well as in America, upholds this theoretical exposition most satisfactorily.

The rationale of the favorable action of all creosote preparations in pulmonary affections is not yet definitely elucidated, and should receive further investigation.

Dr. Andrew H. Smith believes that the nascent creosote liberated in the intestinal canal, circulates in the blood and has a direct exterminating effect upon germs wherever it comes in contact with them. Some observers believe that the entire body is permeated with the antiseptic material that is thus introduced, and thus bacteria causing various diseases are met and destroyed. Others claim that the action of the creosote preparations is simply that of a neutralizer of the toxins produced by the bacteria. Whether it be merely a restriction of the development of the bacteria or complete annihilation of them, the fact remains that after the exhibition of thiocol, the toxic manifestations are greatly reduced.

My own experience with thiocol has been quite extensive and varied. I have used it in acute and chronic bronchitis, pneumonia, and more particularly in phthisis pulmonalis in which latter disease I have observed its action in over 20 cases.

Resolution in bronchitis I found to take place much sooner than usual, and in pneumonia the temperature could be reduced 4 degrees in twenty-four hours; the areas of dulness and the bronchial breathing rapidly diminished, and free and easy expectoration was established phenomenally early.

In tuberculosis the night-sweats were stopped almost from the first, the fever was markedly reduced, expectoration made easier and less purulent where mixed infection existed, while the cough became less persistent and annoying. The most marked effect, however, was upon the general condition of the patient. There was less nervousness, better tone to the nervous and muscular system, the appetite was stimulated and asimilation improved. At no time was there any derangement of digestion or irritation of the stomach. The dose varies according to the severity of the disease. I usually give thiocol three times a day, starting with 5-grain doses and gradually increasing the dose each day, especially in phthisical cases, until a maximum of from 30 to 45 grains is reached.

In thiocol Roche we have an elegant and efficacious creosote preparation that bids fair to be one of our most valuable modern therapeutic agents, and, in closing, I can give no more worthy testimony of its efficacy than by simply quoting a few cases of phthisis in which I have used it:

*Observation I.*—Mrs. P. S., aged thirty-one years, took a severe cold, one year ago, followed by bronchitis; had night-sweats and hectic fever; heart is excitable and irritable; both lungs consolidated with crepitant and sibilant râles throughout, expectorates a good deal; sputum shows the presence of the tubercle bacillus. She was put on thiocol in doses of 5 grains 3 times a day and this was gradually increased by one grain each time until she was taking 10 grains at a dose, making in all a total of 30 grains *per diem*. The night-sweats gradually disappeared as well as the fever, so that at the end of one month she had no night-sweats, scarcely any fever, the râles were less sonorous, expectoration was lessened, and she had gained somewhat in weight. She is still under observation and steadily improving.

*Observation II.*—Mr. H. B., aged fifty years, whose mother died of consumption at forty-four years of age, also one sister who died of consumption at the age of eighteen years; had grip and bronchitis two or three years ago; since then has coughed and expectorated a great deal; has had many hemorrhages, is nervous and impressionable; there are many old pleuritic adhesions at the base of the left lung with dulness at the apex. Right lung is consolidated at the back for almost its entire length; in front crepitant râles can be heard; has a temperature of 102° F. and night-sweats. He was put upon thiocol in 5-grain doses which was gradually pushed up to the maximum of 45 grains a day, with the happy result of reducing the temperature to 99.2° F., lessening the expectoration, and alleviating the cough; the night-sweats disappeared after the fourth day of treatment. He has gone south to avoid the bad weather, but is keeping up his treatment with thiocol.

*Observation III.*—Mr. E. C., aged twenty-seven years; parents both living; four years ago had bronchitis; aspect florid; is impressionable but not very nervous; number of respirations, 18; pulse 82; temperature 99.5° F.; digestion fair; right lung crepitant and sibilant râles at the apex, the entire base consolidated and at a point posteriorly, the evidence of an old pleurisy; at the apex of the left lung, there was a lesion which was the cause of blood in the sputum; he coughed a great deal and raised much thick sputum, which was occasionally tinged with blood; had night-sweats and hectic fever. He was put upon 5-grain doses of thiocol three times a day, which was gradually increased to 10 grains three times a day. His temperature dropped to normal, the night-sweats left him, the expectoration became thinner and ceased to

be tinged with blood, his cough was lessened, he slept better, his appetite increased, and he put on flesh. He is still taking thiocol and there is hope of further improvement in his case.

## ON THE PRESENCE OF SPECIFIC COAGULINS IN THE TISSUES OF VERTEBRATES AND EVERTEBRATES.*

BY LEO LOEB, M.D.,
OF MONTREAL;
FROM THE JOHN H. MOLSON LABORATORIES OF PATHOLOGY AND BACTERIOLOGY, MCGILL UNIVERSITY, MONTREAL.

In previous investigations† I found that the blood-plasma of the lobster coagulates under the influence of a piece of fibrin of the lobster, and that a piece of the muscle of the lobster has a similar effect. The fibrin of the blood of rabbits or rats, or the muscle of frogs, were without effect. I concluded that these facts point to a multiplicity of fibrin ferments in different species, and to a similarity or identity in different tissues of the same species of animals. "This specificity in the one case and the want of it in the other case corresponds to a similar specificity and want of specificity which has been found to exist with the precipitins obtained through injection of certain body fluids or albuminous substances into different species of animals."

I further investigated if a specificity of the substances causing coagulation existed also in the tissues of vertebrates. In a preliminary communication "On the Coagulation of Blood in its Relation to Thrombosis and the formation of Fibrinous Exudate,"‡ after an investigation of different classes of vertebrates, I published briefly, among other results, the fact that the same specificity of the tissue coagulins was found to exist in vertebrates and evertebrates. Since Woolridge's investigations it is known that extracts of various animal tissues have a marked effect on the coagulaton of the blood. Delezenne found that contact with the liquids and tissues of the wound has a decidedly accelerating effect upon the coagulation of the outflowing blood in birds. The blood of birds collected in the extract prepared from certain tissues of birds coagulated much more rapidly than it would have done otherwise. He found that extracts of other than bird tissues were less active, and believed that this marked activity of the tissues of birds compensated for the slow coagulation of bird's blood which takes place if contact of the blood with the tissues is avoided.

Conradi, who recently compared the influence of tissue extracts on the coagulation of blood before and after autolysis had taken place, seems to have assumed the existence of an approximately equally strong influence of extracts of fresh tissues upon the coagulation of the blood. A few weeks before my second paper on the coagulation of the blood appeared Hewlett published the observation* that an extract of goose liver did not have an accelerating effect upon the coagulation of dog blood. An extract of dog liver, however, did have an accelerating effect upon the coagulation of bird blood. He looked on this fact as suggestive ("Andeutung") of a specific action of the tissue extract of birds.

I now wish to state briefly the result of several series of experiments in which, in each case, the influence of tissue extracts of different classes of animals was tested upon the blood of a mammal, bird, reptile, amphibian, and arthropod. Only such a comparative investigation is able to demonstrate the specificity of the action of tissue extracts upon the coagulation of the blood.

1. *Experiments on the Blood of Rabbits.*—The following extracts were tested on rabbit blood: rabbit muscle, rabbit liver, cat muscle, cat liver, guinea-pig muscle, guinea-pig liver, pigeon muscle, pigeon liver, and, as a control, 0.8 per cent. sodium chlorid solution was used; the influence of the blood-clot and serum of the pigeon and guinea-pig, and of the serum of the rabbit were also tested. In each case 2 c.c. blood obtained from the carotid of a rabbit through a canula were received in 4 c.c. of the different extracts or of sodium chlorid solution containing the serum and blood-clot, or of a pure sodium chlorid solution. In five series of such experiments identical results were obtained. No marked difference between the action of the blood-clots or blood-sera used was found to exist. Among the tissue extracts, however a typical difference was present. Extracts of rabbit muscle and rabbit liver were by far the most powerful in causing coagulation of rabbit blood. All others were decidedly weaker, occasionally even less effective than a pure sodium chlorid solution. No marked difference between the extracts of the liver and of the muscle of the various species was found to exist.

2. *Experiments on the Blood of Birds.*—A large number of experiments were made with goose blood. In this case the method employed was somewhat different, inasmuch as the blood plasma was used and in most cases not extracts of tissues but solid pieces of the tissues were employed. The tissues of birds were found to be the most effective ones in causing coagulation. Among the tissues of various birds no marked difference in efficacy has been found so far. Among the tissues of other classes of animals typical differences were found to exist. The tissues of the cat and also of the dog were found to be much more active than the muscle of the guinea-pig and of the frog. The blood-clot of birds, however, was not more active than the clot of mammalian blood.†

3. *Experiments on the Blood of Turtles.*—In these experiments large turtles had to be used be-

* These investigations were carried out under a grant from the Research Fellowship Fund of McGill University.

* Archiv. f. Pharmacologie u. experim. Pathologie, June, 1903.
† For further results obtained on the blood of the goose, I refer to my paper in the Montreal Medical Journal, and to the full paper which shall appear later.

cause in small turtles the blood flows out too slowly. For want of material only two experiments have been made so far. One c.c. of the blood of the turtle was collected in 2 c.c. of the extracts. Turtle liver, turtle muscle, rabbit liver, rabbit muscle, pigeon liver, pigeon muscle and 0.8 per cent. sodium chlorid solution were used. Extracts of turtle tissues were in these experiments the most active ones. In one experiment the difference between the tissues of the turtles and all other tissues was very pronounced; in the other experiment such a difference was still present though not so marked, presumably because in this latter case the blood was flowing from the animal at a much slower rate.

4. *Experiments on the Blood of Frogs.*—For these experiments bullfrogs were used. One-half c.c. of the blood was received in various test tubes containing each 1 c.c. of the extract. Extracts were prepared from guinea-pig muscle, rabbit muscle, rabbit liver, pigeon muscle, pigeon liver, frog muscle, frog liver, and as a control 0.8 per cent NaCl. solution was used. Seven experiments were made with identical results. Extracts of frog tissues were in each case by far the most active ones, all other extracts having not rarely even a somewhat inhibitory effect upon the coagulation of frog blood as compared with the action of a 0.8 per cent. sodium chlorid solution. Extracts from muscle and liver do not differ materially.

5. *Experiments on the Blood of the Lobster.*—Further experiments were made confirming and enlarging the results previously obtained. Various tissues and blood-clots of vertebrates were tested as to their influence on the coagulation of the lobster plasma. All vertebrate blood-clots and tissues were found to be without effect.

We see that the blood-clots of several species of vertebrates tested on vertebrate blood were not markedly different in their activity and did not show any specific influence upon the coagulation of the blood of their own species. With regard to the arthropods, however, the ferments contained in the various blood-clots become specific. The clot obtained from lobster-blood is active in causing coagulation of the lobster-blood. Clots obtained from vertebrate blood are ineffective, though the clot obtained from lobster-blood has a slight effect upon the coagulation of goose-blood.

These experiments prove the existence of *specific* coagulins in the tissues of all the species of animals so far tested. We may therefore speak of specific isocoagulins existing normally in the animal tissues, in so far as the coagulins are specific for the blood of the species from which they were obtained. The limits of this specificity remain yet to be determined. We saw that extracts of the tissues of rabbits, as compared with the action of guinea-pig tissue extracts, act specifically on the rabbit blood. We found, however, the tissues of the pigeon about as active as the tissues of the goose in their effect upon the coagulation of goose-blood. The methods used in these two cases were not identical, as stated above. The specificity which has now been established does not exclude the possibility that the coagulin of one species may not also act, though less strongly, upon the blood of another species. In addition, substances exist which have a non-specific influence upon the coagulation of the blood of different species of animals, as, for instance, Witte's pepton and leech extract. Such non-specific substances exist also in the tissues of other animals, as, for instance, in the crab and, perhaps, in certain vertebrate tissues.

The coagulins therefore are analogous to certain substances which are obtained through the process of immunization, namely, the agglutinins, precipitins, and lysins. They also resemble these substances in being decidedly useful to the animal in which they are found.

Each species of animal so far tested has specifically adapted means for preventing a dangerous loss of blood. The origin of this mechanism is a problem of great interest. Even granted that those animals of each species which did not possess specific coagulins were destroyed in the struggle for existence, such a selective process does not explain the origin of these useful specific substances. We would not be satisfied if the attempt were made to cut short our investigations into the origin of the specific products of artificial immunization by the hypothesis that they were due to selective changes which took place during the processes of evolution. In the case of artificial immunization we study experimentally the changes which take place when an animal is immunized. In the case of the coagulins, we have to deal with specific substances existing naturally and not created by artificial immunization. A comparison of the specific relations existing between the fibrinogen and the tissue coagulins of each species of animals, and of the specific relations existing between a substance introduced experimentally into an animal and the new substance arising in the body of the animal suggests that also in the case of the coagulins the specificity has been acquired through a process of auto-immunization. We would have to assume that the presence of a certain fibrinogen produces a specific tissue coagulin or vice versa.

Another aspect of the specific relation between the fibrinogens and the tissue coagulins may be briefly mentioned. We have here to deal with another instance of an interdependence between apparently not connected organs and tissues—as it is for example, known to exist in the case of the thyroid and the ovaries in their relations with other tissues, or as it is also known for enterokinase and trypsin.

Is the effect of different tissues upon the coagulation of the blood due to the lymph circulating in the organs? Is the lymph the only carrier of the specific substances acting upon the blood?

The following cosiderations make it improbable that the lymph is the carrier of this specific substance. A careful washing out of a piece of tissue does not materially diminish the influence of

the tissue upon the coagulation of the blood. Further, the lymph obtained from the thoracic duct of the dog has approximately the same power as a blood-clot of the dog to induce the coagulation of the blood plasma of the goose. On the other hand, the muscle of a bird, even if it has been previously washed out, has an equal or usually even a greater power of causing the coagulation of the blood plasma of the goose than either the goose or dog clot.

Finally, it can be definitely proven that the influence a piece of muscle of a lobster has upon the coagulation of the blood-plasma of the lobster is caused by a substance derived from the muscle itself and not from the circulating body fluid.

---

## PUSTULATION AND ITS ACCOMPANYING SECONDARY FEVER A COMPLICATION AND NOT AN ESSENTIAL SYMPTOM OF SMALLPOX.

BY JENNIE G. DRENNAN, M.D., C.M.,
OF ST. THOMAS, ONTARIO, CAN.

Smallpox:—"An acute infectious disease, characterized by an eruption, which passes through the stages of papule, vesicle, pustule and crust. The mucous membranes in contact with the air may be affected. Severe cases may be complicated with cutaneous and visceral hemorrhages." According to this definition, which is the one generally sanctioned, the pustular stage with its attending secondary fever is considered as an essential feature, and is not regarded, as I regard it, as a complication due to the infection of the essential lesion of the disease by pus organisms present in the skin. These are present more or less at all times and only require some morbid condition to excite them to action, one, which provides a suitable soil for their development and display of their pathogenic characteristics. They are lurking foes, vultures, which ever hover around the battlefield. Their number is legion or few according to the cleanliness and healthiness of the skin; an uncleanly skin is always an unhealthy skin, for it, like any other organ, rebels against any factor which interferes with its functions, and dirt will do this, producing a lowered vitality of the tissues.

Smallpox, in common with other zymotic or germ diseases, is caused by a micro-organism gaining access to the body, either by inhalation through the respiratory organs or through the skin; from its characteristic cutaneous lesions, one is led to believe that the latter is principally the organ of entrance. On account of the supposed germicidal properties of the red-blood corpuscles, it is not likely that it is by the circulation. It is doubtful if organisms ever gain access to the tissues by this agency. This particular organism has not as yet been isolated, a fact which appears rather strange, but which is in all probability due to search for it not being instituted at the proper time, which is when it is at the height of its activity and before nature has attacked it, *viz.*, in the initial stages, when it may be found in the shotty papules, as yet unattended by an inflammatory reaction. These are the camping-grounds of the detachments of the enemy. Having gained access to the body by some channel they develop in the cutaneous tissue and mucous membrane near the surface, rarely and in only very severe cases are the more internal mucous membranes the seat of lesions caused by the germs themselves being present; cases in which nature and art being unable to cope with the foe, it has invaded other territory than that which it first planned to attack. The visceral lesions usually observed are due to toxin irritation and not to the presence of the germ itself; these toxins being carried by the blood and lymphatic vessels. The period of incubation varies from seven days at the earliest—I know of one case in which the disease manifested itself six days after exposure, the patient being on in years—to fourteen or more at the latest. Like all other organisms, vegetable or animal, it lives its little life, is begotten, takes in nourishment, elaborates it for its own use, excretes waste products, grows and begets its kind. During this period of incubation the number of organisms rapidly increases and with the increase in number there is consequently an increase in the amount of microbic excretion in the human body or host of the parasite, for such it is, as it deprives the cells of the tissue it has invaded of their lawful amount of nutriment, thus rendering them more vulnerable later on to its poisonous action. It is like the enemy that plunders the inhabitants of a district before the avenging force comes up. When such an amount has accumulated that its irritant effects are felt by the host—the harassed party has reported at headquarters and the governing body undertakes to protect them—his channels of elimination not being adequate for the draining off or removal of this matter—toxins—it poisons his system, the finer and more delicate structures feeling the effects first: the host rebels and constitutional symptoms, the first evidence of the presence of the organisms are manifested; this is the stage of invasion. In this particular disease the initial symptoms are severe frontal headache, lumbar pain, sometimes scarlatiniform or measly rashes corresponding to the areas supplied by the irritated lumbar nerves in particular; vomiting, chills and elevation of temperature. The toxins circulating in the fluids of the body in sufficient amount at last irritate the nervous system and through the sympathetic institute an inflammatory reaction. Nature ever seeks to thwart the effects of any foreign substance, animate or inanimate, by this method, in all disease the angioneurotic factor is present. The more delicate tissues are the first to suffer. It is not necessary that the micro-organisms themselves shall be present in these tissues, their toxins alone will be sufficient.

The symptoms of the stage of invasion are a warning to nature that an enemy is at work and that immediate action on her part at the camping-ground of the foe is required and this is exactly

whither she directs her forces; she sets up a severe acute inflammatory reaction around the shotty papules, for herein lies the foe. These initial symptoms are all evidences of the poisoning of the finer tissues, disturbance of the nerve centers and nervous tissue. On the third or fourth day of the disease red papules appear first on portions of the body where the skin has been more exposed to irritation and less vascular portions, and parts exposed to air especially on the forehead and at the wrists; these are also situations in which one variety of epidermis is merging into another, the more delicate cuticle of the face to that of the scalp; that of the forearm to the denser of the hand. Points of cleavage are always weak points. The lesser vascularity of such parts renders inflammatory reactions less formidable to the enemy and thus allows him more time in which to produce his poisonous weapons—toxins. Later the eruption spreads over the face and extremities and finally appears on the trunk.

That the source of entrance of the micro-organism to the body is mainly, if not altogether, by the skin, is likely for it is the exposed portions of it that are first attacked, involvement of other portions occurring later probably from auto-infection. The severity of the disease is always proportionate to the number of lesions on the face. "If upon the face they are as thick as sand it is no advantage to have them few and far between on the rest of the body." While this statement serves to show that great face involvement denotes great severity of the case, still it must lessen the danger to have only a few on the body, for each lesion represents a collection of the foe; but if from great face involvement we naturally expect also great trunk involvement, and it does not occur the view may be taken that the foci are situated in the latter position; but that Nature is unable to attack so great a force and these foci on the trunk escaping inflammatory reaction still continue to pour forth toxins into the body, remaining shotty papules instead of becoming red inflammatory papules; inflammatory reaction having the effect of preventing this continuance of the elaboration of toxins by destroying the micro-organisms as will be explained later on.

The red papule consists in the center, of the germs which formed the shotty papule, surrounded by the products of inflammatory reaction (liquor sanguinis and leucocytes), the vessels surrounding the papule being in the state in which they are found in inflammation of a tissue. This is Nature's method of attacking the foe, she surrounds him and hems him in and sends her warriors, the leucocytes, to destroy him and also another factor, the liquor sanguinis. Each papule is a small well-defined battlefield; the center of it is occupied by the foe, which multiplies indefinitely and elaborates toxins in increasing amounts; the circumference contains the factors of Nature arrayed to cut down the enemy. Nature in her attempt to destroy the pathogenic factor does not in some distant organ of the body produce some substance inimical to its existence; but she at once, through her angioneurotic, her nervous circulatory combination surrounds him by an area of inflammation and hems him in. All the different phases of an inflammatory reaction are gone through; dilatation of vessels, acceleration of blood stream, followed later by retardation and finally stasis; with escape of fluid and corpuscles—the red only in the most severe reactions. The vessels contain an increased number of white-blood cells for a leucocytosis has occurred to enable Nature to successfully attack the enemy and the blood-making organs have been called upon to increase their output of white corpuscles—enlargement of the spleen is often noticed as also glandular enlargement.

The first portion of the liquor sanguinis which passes from the vessels into the tissue surrounding each clump of organisms—shotty papule—is absorbed along with the toxic matter from the organisms, as lymphatic circulation is not as yet impeded; but a little later on the leucocytes in ever increasing numbers escape also from the dilated vessels into the tissue; those in the front ranks fall victims to the toxins of the micro-organisms, but others from the rear take their places. The dead bodies of the first have a function to perform (for dead as well as living they are useful); by their death their contained fibrin ferment is set free, this acts on the fibrin-forming factors contained in the liquor sanguinis and fibrin is formed, which entangles in its meshes the pathogenic organisms along with some of the blood cells—the fly is now caught in the spider's web and the enemy is entrapped and slain, for, bathed in its own toxic matter it now poisons itself.

Every animal has within its own self the means of destroying itself, retained excrementitious matter means auto-intoxication and in this case, it also retains its toxins and lies entangled in a clot containing them. It is a Black Hole of Calcutta. This clot is the area of coagulation necrosis noticed on the section of a papule. It is creamy white or greenish yellow in color from not containing colored corpuscles. During this inflammatory reaction many leucocytes are forced into the deeper layers of the skin, the papillæ of the cutis vera, from which they later on pass outward and taking on the characteristics of the cells of the cuticle repair the destroyed skin; for the organisms in the heyday of their power caused the death of many cells by depriving them of their normal amount of nutriment and also by their toxic action on them. The destruction so far in the disease is not so marked as what may result from the effects of the secondary infection by pus organisms. Nature having performed the great master-stroke in slaying the micro-organisms, now that they are dead in her hands gradually lessens the reactive inflammatory action and the escape of leucocytes and fluid is restricted. What fluid does escape is prevented from being carried off at first by the lymphatics by pressure from the exudate on these vessels; this fluid no longer be-

ing necessary for the formation of a clot collects in the intercellular spaces of the tissue forming the outer zone of the papule; the coagulum contracts and the serum being squeezed out of this by the contraction, also increases the amount of clear fluid and thus form the vesicle—the vesicular stage. The coagulated area in the center of the papule prevents the fluid from distending it in the center, hence the umbilicated or depressed vesicle, for the fluid is forced to expand the periphery alone. If fluid were injected into the tissues surrounding the abdominal umbilicus it would distend the former but not the cicatrix: this is on the same principle—for what is a scar but organized fibrin?

With the appearance of the characteristic eruption in its first phase, red papules, the temperature falls and the patient becomes comfortable from a cessation of the other initial symptoms also, and if no complication, such as pustulation, arose the duration of the disease would be short. The irritation from toxins being removed (for with the destruction of the organisms this source of irritation has been removed), the circulation resumes its normal state; pressure from inflammatory reaction being removed the lymphatics again assume their function and the serum in the vesicles is absorbed. "Cases in which hemorrhage occurs into the vesicles at once dry up," showing that depletion of the inflammatory area hastens absorption of fluid by renewal of pressure.

In chickenpox the vesicle is not umbilicated, because in this case, due to the lesser virulence of the toxins, the circulatory disturbance is less—fewer leucocytes escape and a coagulum is not formed in the center of the papule.

Unfortunately, instead of vesiculation being the final cutaneous lesion in smallpox there is a subsequent one,—pustulation, this being, in my opinion, the result of a secondary infection by pus organisms, which are ever present in the skin. Most probably those present at the time of the entrance of the smallpox organism would perish from the toxins excreted by the latter, for if they did not we should have evidence of pustulation earlier than we do; but on the cessation of the excretion of the toxins of the smallpox germs by the death of the latter, these pyogenic organisms will find the vesicular fluid a suitable medium in which to flourish; it is not a highly toxic fluid because the toxins have been taken up by the organisms themselves and lie inert in their dead bodies, toxalbumins. This vesicular serum soon becomes turbid from the rapid development of these pus germs and the vesicle becomes a pustule, the coagulated area is broken down and the pustule assumes a globular shape, thus differing from the umbilicated vesicle. From the toxins excreted by these organisms and probably from the liberation of toxic matter from the decomposed coagulum a secondary systemic irritation results with a rise of temperature and a second inflammatory reaction around the foci of infection. These later foes must be dealt with in the same manner as the first. The temperature again falls when the foe is overcome and convalescence is now entered upon. It was stated before that when hemorrhage occurs into the vesicles, they dry up and the disease is aborted. This is due no doubt to the germicidal action of the red cells of the blood on the pyogenic organisms in the vesicular serum. The extent of scarring or pitting depends on the extent of the pyogenic mischief; if it is extensive the leucocytes stored up in the papillæ of the skin for reconstructive purposes are destroyed and new cells are not forthcoming to replace the old which have perished.

It is said by the highest authorities that the disease is infectious throughout its whole course, that the contagium exists in the secretions and excretions and in the exhalations from the lungs and skin, the dried scales of the latter constituting by far the most important element. There is a doubt in some minds as to whether the disease is infectious before the eruption develops and in the mind of the laity it is supposed not to be contagious until the stage of pustulation and scabbing is reached. I believe that the disease is infectious in its earliest stages, when the germs are developing in the skin—shotty stage—and throughout the course of the disease. Germs work their way from the camping-ground into surrounding tissue and pass to the surface as the lesions are situated in the skin and mucous membranes near the surface, here they are given off in excretions and secretions passing from these parts and are also thrown off in the scales of epidermis and epithelium which are normally shed; this shedding at the termination of the disease will be more abundant but it is, however, going on all the time. The germs contained in these may not be in an active state, but once taken into a new host they quickly take on active properties and cause the disease. In an epidemic at present prevalent those exposed presented the symptoms just fourteen days after; they must have taken in the germs while the first patient was in the earliest stages of the disease for he was at once removed.

I do not consider the well-developed red papule, vesicle and pustule particularly infectious, but rather the surrounding skin which contains dormant germs; for in the other cases the germs have been attacked by Nature. The epidermis being a non-vascular structure deriving its supply of nutriment from the vessels of the underlying cutis vera, will not be engaged in the active inflammatory reaction. It suffers from its supply of nutriment being curtailed on account of circulatory disturbance and is more abundantly and rapidly shed with its dormant micro-organisms. The pustules are contagious by reason of their pyogenic cocci, not from their smallpox germs, unless a few may have survived.

The cure of germ disease depends on the destruction of the organisms by their own excretions; this is Nature's method and if unaided she cannot accomplish it, art must be called in to assist her; but to be successful it must be by a means analogous to Nature's plan. In serum

therapy we have this. The nearer we approach to the understanding of her methods, the simpler will be our treatment and the less empiric drugging will there be. If, in smallpox for example, organisms enter a host; the skin being the point of attack, they multiply, but there is as yet no inconvenience suffered by the surrounding tissues, save that the germs deprive the cells of their normal amount of nutriment and thus render them, later, more vulnerable. While at first, on account of their as yet small numbers the micro-organisms have not excreted more toxic matter than can be drained from the system by the organs of elimination, the host has not suffered: but if his organs are at the time in a dilapidated condition elimination will not be so thoroughly carried out and systemic poisoning will be the sooner established with its initial symptoms and succeeding inflammatory reaction: but if they are acting normally the stage of systemic invasion will be later in appearing. At last, due to the rapid increase of germs and, therefore, the enormous increase of toxic matter, even these so far healthy organs cannot adequately remove it and systemic poisoning occurs.

Since the introduction of the so-called antitoxin treatment of diphtheria much has been written concerning a substance being formed in the body during disease, which neutralizes the effects of the toxins and renders them harmless. This has led bio-chemists far afield and has opened up glorious fields for research: but is this the case? I do not believe that the so-called antidotal substances are formed. All animals excrete substances which if they are retained within the body, or if re-admitted will cause their own death; but no antitoxic substance is formed to neutralize them. Why, then, in the case of disease from the toxins of micro-organisms? Such a theory will not stand the test of future research. The serum injected in diphtheria is the serum of the blood containing the toxins of the diphtheria micro-organism. By its injection Nature is anticipated and a systemic poisoning is hastened, whereby the inflammatory reaction is brought into play and the organisms so much earlier attacked. Constitutional symptoms are accelerated and intensified but the cure is brought about so much earlier than if Nature is unaided. This is the curative effect of the injection of a toxin serum. There is also the protective effect: one attack usually confers immunity to this disease on the person for some time, if not for life, and so does the introduction of the serum prevent the exposed from contracting the disease; here the enemy on gaining access to the body is at once dealt with: Nature is prepared for him. It is much better to deal a decisive blow at the foe early in the disease, for then the system is in a better condition to react: the toxæmia from increased waste products and the semi-starvation have not as yet been felt by the body; prolonged action weakens the resisting forces. In many diseases, as yet, instead of serum treatment being used germicidal drugs are had recourse to: aiming at destruction of the foe with carbolic acid, mercury and others, and, as I have shown in an article on the "Action of Ferric Chloride in Erysipelas and Allied Conditions," in the *Medical Record*, aim at hemming in a foci of infection, thus imitating Nature's method. The treatment of smallpox and all other germ-caused diseases should be by means of toxin serums. It may be asked why introduce a substance similar to that which is causing such severe constitutional symptoms; but in this lies the cure, severe constitutional symptoms evidence on the part of Nature the ability to react. Cases of smallpox with most marked initial symptoms are usually the ones of shortest duration and less severe future course. Ambulatory attacks of typhoid fever are often fatal.

*Vaccination.*—The inoculating of man with the virus of an eruptive disease of the cow; a local pock with constitutional disturbances is produced and protection from smallpox, more or less permanent, is obtained.

Cowpox, if not the same disease in the cow as smallpox in man, is very similar. In the cow it goes through the same initial symptoms; papular, vesicular, pustular and scabbing stages. It is during the vesicular stage that the vaccine is removed for vaccination purposes. Now, what is present in an umbilicated vesicle at this time? An area of coagulation necrosis—clot—and serum containing pus organisms, which have entered from the surrounding unaffected skin and are rapidly multiplying; the area of coagulation necrosis contains fibrin; broken down leucocytes, free toxin; toxalbumins formed by the action of the toxins on the germs and some germs, which may have not been destroyed and are lying quiescent, ready on removal to set up a new infection. In vaccination, what do we use, the serum of the vesicle which is multiplying pyogenic organisms or the clot or pulp? The best firms who prepare vaccine tell us that they prepare it from the pulp. If this is so we are inoculating the person with the free toxins, undestroyed cowpox micro-organisms and toxalbumins from which the toxic element may be liberated. In this aseptically prepared vaccine constitutional symptoms and local pock do not appear until seven or eight days after inoculation, but in the varieties of vaccine which contain both the serum of the vesicle and pulp—the older kinds—constitutional symptoms and the local pock appear as early as the second or third day and the disturbance is more marked. No doubt the presence of pyogenic cocci in the serum is responsible for this; pyogenic organisms have a short incubation stage and, already having multiplied in the serum, they are fitted for action, the first constitutional disturbance is no doubt due to them and this is quickly followed up by that of the cowpox germs. In vaccination as well as in smallpox the stage of pustulation is a complication. In the aseptically prepared vaccine carefully inoculated into a clean scarified area with the skin surrounding it kept clean pustulation should not occur. What are we doing by this vaccination process? Merely from a small laboratory in the human body elaborating sufficient toxin to

render the person vaccinated immune to smallpox. Immunity depends on the presence in the body of an agent harmful to the germ causing the disease. The same effect is produced by injecting as a safeguard against other diseases, serums obtained from animals susceptible to such diseases and injecting these serums, which contain toxins into the human body; cholera, typhoid, diphtheria, and so on; why not do the same in smallpox? Jenner's great discovery has been a boon of untold good to humanity; but with all due regard to the great discoverer, it is only a half method and in this day of toxin serumtherapy it ought to be relegated to its proper place of what has been best, but which is not now best. With the introduction of a toxic serum as a protective agent many complicatory symptoms and disturbances would be done away with and in the case of exposure to the disease the protective action would be more rapid. It certainly is the protective and curative treatment of the future. This serum would have to be taken from the cow, as the diphtheria toxic serum is taken from the horse. The period of invasion or initial symptoms would be the time, when the blood is saturated with toxins, veins in the vicinity of the part affected the udder, would probably yield the greatest amount. The author will feel grateful to any one, who will take up the subject, where she has been compelled for the present to stop, and who will carry it through.

Do the toxins of other diseases than the one in question exert an immunizing effect on the person who has been the subject of their ravages? I fancy so, although the protection may not be so lasting. In an epidemic of smallpox, which occurred in the Toronto General Hospital patients suffering from typhoid fever showed marked immunity, some years ago under an incorrect diagnosis, a case was admitted to our own hospital; there was only one other patient in the ward at the time, he was suffering from purpura hemorrhagica and could not be vaccinated; but although exposed for some time to smallpox, he escaped infection. Later on, some weeks in fact, he carried the infection to all the people he visited. In a slight epidemic, from which we are now emerging, all the members of one family save the father and a girl of eight or nine years of age have been attacked. This child had an attack of scarlatina followed by severe inflammatory rheumatism eight months previous. By Dr. Graw, of Buffalo, it was observed that vaccination lessened the severity of an attack of influenza.

*Treatment.*—In conclusion, a word as to the treatment of smallpox, and the prevention of pustulation will not be out of place: (1) Injection of a toxic serum obtained from a cow suffering from the initial symptoms of cowpox. This toxin serum should be injected in the stage of invasion, as soon as symptoms have been observed; (2) cleanliness and disinfection of the skin, to prevent an accumulation of pyogenic organisms and the internal administration of calcium sulphide to prevent pustulation, as in furunculosis; (3) opening of all vesicles, thereby removing the vesicular fluid, which is such a medium for the growth of the pyogenic organisms and the painting of each opened vesicle with aseptic collodion. The prevention of pustulation will abolish pitting, for in the early stages of the disease the cutaneous involvement does not extend into the cutis vera; (4) treat symptoms as they arise.

Smallpox is an acute infectious disease, caused by a special micro-organism not yet isolated, passing through a stage of incubation during which there are no symptoms, followed by a stage of invasion with initial symptoms in which the shotty papules may be detected, followed by the red papular and vesicular stages.

## MEDICAL PROGRESS.

### MEDICINE.

**Antistreptococcus Serum.**—The present status of this subject has been thoroughly investigated both clinically and experimentally by Menzer (Münch. med. Woch., June 30, 1903). Over 100 cases were under observation and the author's main point was to determine the indications and contra-indications for the use of the serum. The value of this remedy has lately been largely overrated and a warning is extended against its indiscriminate employment. The serum as shown by animal experimentation, is effective by stimulating phagocytosis, and the organism itself therefore assumes an important rôle in the fight against the streptococci. When this function is no longer possible, the administration of the serum is of no value. In addition to the destruction of the pathogenic organisms, the body is also compelled to get rid of the dead bacteria and the cells. In those cases where there are walled off collections of pus, the use of the serum is contra-indicated, unless surgical interference is also practised, as the serum increases the resorption of the toxic purulent products. The serum gives the best results in acute cases, if given in large doses. In chronic mixed infections it should only be given if the condition of the patient, and particularly the lungs, make it probable that the organism is still able to attack the chronically inflamed foci of inflammation. The serum should be given in small and gradually increasing doses. Only those sera are effective which are freshly prepared from streptococci of human origin. Standardizing the serum by animal experimentation has thus far afforded no means of judging the degree of curative power in the human subject, and for the present the effect on the individual is the only measure of its action.

**A New Method of Hemo-Alkalimetry.**—Most of the methods for the purpose of determining the concentration of alkali in the blood depend on the reaction with some chemical indicator and require for their application a volume of blood only procurable by the scalpel or the cupping glass. The results in such cases are only approximate and do not determine delicate variations. A new method for determining the neutralization of the blood at an exact and definite point, which is free from the inaccuracies of test papers and does not react solely to certain of the complex ingredients of the plasma, but shows the point of neutralization of the whole blood, is presented by Arthur Dare (Bull. Johns Hopkins Hosp., July, 1903). Blood, when examined with the spectroscope, gives the characteristic spectrum of oxyhemoglobin, unless changed by the absorption of certain gases or the introduction of sub-

stances that modify the composition or functional conditions of the plasma. As the blood is diluted and examined in a stratum of a certain thickness, the absorption bands of oxyhemoglobin are observed to fade away, but are made to reappear when this stratum thickness is increased. When, however, blood is triturated with an acid reagent, the spectrum of oxyhemoglobin disappears and cannot be restored by the addition of an alkali or by increasing the stratum to the maximum, which is capable of illumination for examination spectroscopically, hence the spectrum of oxyhemoglobin may be removed by dilution or by neutralization, in the latter case the hemoglobin is changed and its characteristic spectrum is destroyed permanently, while in the former it can be made to reappear by increasing the concentration of the hemoglobin. The new method is based on this observation. The basic material is neutralized by a solution of tartaric acid, gm. .075, to distilled water, c.c. .200. The special instrument devised by the author for this test consists of a capillary blood-tube and a reagent pipette. The latter contains the acid reagent. The lower end of the blood-tube is then examined with the spectroscope, and if the bands of oxyhemoglobin are present, the acid is added carefully drop by drop, and when the bands suddenly disappear, the observation is at an end. It is then only necessary to read the result from the scale on the test tube, which is graduated in cubic centimeters and the equivalents expressed in milligrams of sodium hydrate to 100 c.c. of blood. The author has devised a special scale of equivalents, in mgs. of sodium hydrate to 100 c.c. of blood. There is a more or less constant relation of the alkalinity of the blood to the color index, and the author has attempted to make this the basis of comparison. For this purpose some 75 cases were examined. In enteric fever a marked decrease in alkalinity is the rule. This is also true in tuberculous disease with glandular involvements, while with tuberculous meningitis or peritonitis the alkalinity shows an increase or falls late in the course of the disease. In gastric ulcer there is a fall in the alkalinity below the color index, while gastric cancer shows an alkalinity above the color index. The anemias all exhibited a decided fall in alkalinity, while observations in chlorotic subjects showed the alkalinity to follow closely the normal color index. The administration of excessive amounts of sodium bicarbonate had no effects on the hemoglobin tests. In splenomedullary leucemia the alkalinity suffers a marked decrease, while in splenic anemia and cholemia it shows a rise. Catarrhal jaundice and amyloid liver both raise the alkalinity of the blood; cholelithiasis presents an evident decrease. Croupous pneumonia, phthisis, influenza, acute appendicitis, even in the presence of a frank leucocytosis, showed an increased alkalinity, while investigations upon malarious subjects appear contradictory. The relation that the alkalinity bears to the excretion of urea still needs investigation. These studies tend to show that in those diseases which present a marked decrease in the alkalinity, they at the same time exhibit a marked increase in the quantity of urea eliminated.

**Obliteration of the Superior Vena Cava.**—While signs of compression of the superior vena cava are not very uncommon in cases of aneurism of the aorta and in mediastinal tumors, instances of complete obliteration of the vessel, with the establishment of a collateral circulation, are extremely rare. W. Osler (Bull. Johns Hopkins Hosp., July, 1903), reports one case under his observation for three years, long enough to make a diagnosis of fibroid obliteration by exclusion, and a second in which the obliteration was due to compression in Hodgkin's disease. Of the 29 cases reported in the literature, thrombosis due to disease within the vein was found in 10. The others were due to lesions outside the vein—tuberculosis, mediastinitis, aneurism, syphilis, periaortitis, carcinoma and fibroma. The symptoms of the condition depend entirely upon the degree to which compensatory circulation has been established. Obliteration of any one of the three great veins of the body may exist for many years with even good health and a completely effected collateral circulation. The clinical summary of the first patient, a young negro, was as follows: Hard work, alcohol and exposure; dyspnea, swelling of the neck and face; gradual distention of the superficial thoracic and epigastric veins; improvement for a time; gradual increase in the size of the superficial veins; the finding of tubercle bacilli; finally, fever, delirium and unconsciousness. The autopsy showed a tuberculous caries of the spine, fibrous mediastinitis with obliteration of the superior vena cava and innominate veins, and a tuberculous meningitis. In the second case there was present a Hodgkin's disease, with compression of the superior vena cava and the formation of an extensive collateral circulation. The disease ran an unusually chronic course and was also marked by the extreme distention of the superficial veins of the thorax and abdomen. There were occasional periods of improvement from the administration of Fowler's solution. At autopsy it was found that the superior cava was completely obliterated by the enlarged mediastinal glands.

**Malarial Cough.**—Attention is again called to the occurrence of cough of malarial origin, by V. Piazza-Martini (Gazz. Siciliana di Med. e Chir., June 4, 1903), who describes three cases which came under his observation in which there was a persistent cough, resisting all ordinary remedies and coming on in paroxysms at about the same hour each evening. In none of these cases was there a malarial history; but the periodicity of the paroxysms, presence of enlarged spleen in two of the patients and absence of other cause, suggested the possibility of malaria in the etiology of the affection. That this diagnosis was correct seems to be proven by the prompt subsidence of the cough after a few days' administration of quinine. The author quotes Sverjvsky's article on malarial cough in which he states that it has all the characteristics of nervous cough and that it may precede or follow the febrile phase of malaria or constitute the sole evidence of malarial cachexia. The latter writer holds that the respiratory condition is not produced by the local action of the malarial toxins upon the mucous membrane, but rather by the effect of the disease upon the general nervous system and especially the sympathetic.

## SURGERY.

**Two Fatal Cases of Partial Thyroidectomy.**—In Egypt goiter is a very common condition, and the operation of hemisection is very frequently done. Frank C. Madden reports (Lancet, June 20, 1903) from the Kasr-El-Aini Hospital, Cairo, two deaths which arose apparently from diametrically opposite conditions. In one, a girl of twelve years, the goiter was tri-lobed. No trouble was experienced in shelling it out but a mass near the isthmus, the size of a walnut, was left. Two days later she had a severe attack of dyspnea from laryngeal spasm. Twelve hours later the hands and feet showed marked signs of tetany and gr. v. of thyroid were given twice a day. This was continued a week, and when all symptoms of tetany had disappeared maltine was substituted for it. Two days later the tetany reappeared and was not checked by renewed administration of thyroid. Finally, twenty-four days after operation she died of tetany of the respiratory muscles. The second case was an antithesis of the first in that death resulted from hyper- rather than hypo-

thyroidization. The wound was packed tightly, but as the patient showed marked restlessness immediately on coming out of the anesthetic, this was removed and the part irrigated with salt solution. Pulse was at this time 144, respirations 52 and temperature 102° F. He was infused with hot salt solution, 1½ litres, all to no purpose. He died twenty-eight hours after operation. It seems to the author probable that, had he pushed the thyroid in the first case he would have saved the first case, but it is interesting to note that the tetany was not controlled by thyroid when it was exhibited the second time.

**Tetanus Prophylaxis.**—The value of tetanus antitoxin as a prophylactic is shown in a series of observations made by J. McFarland (Jour. Am. Med. Ass'n, July 4, 1903) in some 800 horses used for immunizing experiments, in manufacturing different sera, and which were constantly being injected and bled at frequent intervals, and occasionally suffered from local lesions consequent upon the irritative actions of the injected toxins. During this period of four years there was a death-rate from tetanus in spite of all precautions, which at times reached 10 per cent. A systematic immunization was then begun with antitetanic serum, 10 to 25 c.c. of a low grade being injected every three months. The death-rate rapidly decreased and in the second year was reduced to less than one per cent. The practical conclusions to be drawn from these observations may also be applied to the human subject, and the author believes that in all suspicious wounds, which are likely to be followed by tetanus, the antitoxin should be given as a prophylactic measure. The only objections are the cost, poor keeping qualities of the serum, and the method of administration by subcutaneous injection. The latter may be obviated by dusting dry serum on the wound surface, as already advocated by a French observer. Experiments made on guinea pigs by the author, demonstrated that the dried serum fully protected inoculated animals. The advantages of the latter method are that the dry serum preserves its activity indefinitely, requires no instrumental administration, but can be sprinkled from the bottle in which it is dispensed directly on the cleansed wound. It is non-irritating, and neutralizes the toxin in the wound and, being absorbed, also neutralizes the toxin which has been taken up by the patient's blood. The more universal use of the dried serum is strongly urged in all suspicious cases.

**Treatment of Anthrax with Intravenous Injections of Collargolum.**—The introduction into the system of derivatives from metallic silver is attracting very great attention. Dr. Roman Von Baracz (Archiv f. klin. Chir., Vol. 70, No. 2, June, 1903) details the interesting history of three cases of anthrax, which to all appearance were very greatly benefited by this new drug. Large doses, viz., up to cm. xxx were used, since the author had found it to be harmless to dogs even in doses proportionately greater. One thing of some import, to be gathered from his report, is that a severe chill invariably followed the injections, but that this was the exception, if the very newest form of the drug was used. The local treatment of the pustule consisted simply in the application of wet aluminum acetate, so that no one could assume the recovery of the patient and rapid sloughing of the pustule to be due to anything but the collargolum. The author has used this form of treatment in typhoid fever with very good results.

## OBSTETRICS AND GYNECOLOGY.

**Why Minor Gynecological Operations Fail of Effect.**—We may accept as an established axiom that the majority of genital ailments are due either to trauma during accouchement, or specific infection, and that the ultimate results of such accident or infection, *i.e.*, diseases of the uterine adnexa, are not to be relieved by surgical or medical treatment of the original lesion says S. Goldberg (Buffalo Med. Jour., July, 1903). For example: Given an injury of the cervix during labor, which is not repaired at the time of injury or in six months or a year following, an endometritis due to eversion of the contiguous mucous membrane naturally follows, and as there is no structural barrier to limit the process, adnexal involvement ensues. Next, from the constant irritation and increased weight of the uterus, retroversion or flexion occur; these being in the author's opinion the most frequent complications of adnexial disease. In his belief, it is the height of folly to repair the cervix and fasten the uterus by the Alexander method or any modification of it, as it is morally certain that after a year the seeds of disease are sown in the tubes and ovaries and the symptoms, such as pain, metrorrhagia, sacralgia and more or less permanent invalidism are really due to adnexial involvement. Therefore, it is the part of wisdom and safety to open the abdomen, examine the adnexa and treat them radically or conservatively; as in the majority of cases the most of the trouble will be found there. He limits the Alexander operation to acute retroversion of recent standing and holds that all so-called minor gynecological operations, to be of any permanent benefit, must be performed within one year from the time of infliction of the original lesion, and that after a year, Alexander's operation, trachelorrhaphy or curettage or all combined, will be insufficient to restore the patient to health; for the reason that in the majority of cases the adnexa are involved by that time.

**Objections to Vaginal Route in the Treatment of Ectopic Gestation.**—The treatment of this condition has gone through an evolution from a stage of inaction to one of prompt surgical action, passing an immediate one of electrical application. At the present time, J. W. Bovée (Amer. Jour. of Obstet., June, 1903) believes that no physician would fail to recommend surgical treatment, once the diagnosis is made. Failure of diagnosis is due to faulty, early teaching. Symptoms of slight rupture of a pregnant tube may occur particularly in the early stages, at a time when menstruation is expected, or even earlier. The same is true of tubal abortion. In both conditions there may be no evidence of shock, but when it does occur it is typical. Pain and collapse are usually less than are said to be present. Any inflammatory condition of the pelvic peritoneum, tubes or ovaries, may give as much pain, and because of its slight degree, these cases are often mistaken for uterine abortion. Severe internal hemorrhage is not so liable in early rupture as abortion of a pregnant tube in the early stages, as it is then more apt to be slow and may be but slight. The expulsion of a decidua at this time may be overlooked. The author's reasons for preferring the abdominal route in operating on these cases are: (1) The field of hemorrhage can be more quickly reached, taking into consideration the relative amount of time consumed in cleansing the two routes under anesthesia. (2) The condition can be more readily treated and the ligation of blood vessels more readily and certainly performed. (3) The danger from secondary hemorrhage in ectopic pregnancy is markedly less when the blood vessels are ligated than when the removal of the clots alone is practised. (4) Any other important pathological lesion requiring attention may, in suitable cases, be attended to in the same sitting. The shock, as a rule, will be less than when the vaginal and abdominal incisions are both made. (6) The tube can be more readily removed than by the vaginal route. (7) The abdominal route is applicable to all stages of

pregnancy which is not true for the vaginal route in the latter months. (8) The vaginal incision has no place in the treatment of an unruptured pregnancy, while the abdominal incision is the route par excellence.

**Better Care of Women after Labor.**—During the lying-in period, if one is fortunate enough to escape infection, the much stretched, contused and lacerated parturient tract is, says Wm. M. Sprigge (Am. Jour. of Obstet., June, 1903), given no further attention. Somewhere between the seventh and twelfth days, if the patient complains of no special discomfort, she is allowed to get up. The getting-up period is not, as a rule, determined by a careful examination of the pelvic organs, but is dependent upon the absence of subjective symptoms, the progress of involution having never been accurately determined. It is difficult to understand why one part of the parturient tract should be repaired and other lacerations left to shift for themselves, yet much of the practice of to-day is along this line. Nor is it necessary to repair these lacerations within twenty-four hours after labor; some of the lacerations cannot be best repaired at this time, but after twenty-four or forty-eight hours when the edema in the parts has subsided, they can all be repaired and made to heal by primary union. Any lacerations in which large blood-vessels have been torn should be repaired at once. The primary union of the perineum will take place if it be repaired some time after labor. Many of the vaginal lacerations are submucous and cannot be so well detected immediately after labor; these, if neglected, often result in the most severe cases of cystocele and rectocele. They are not hard to repair. The writer agrees with Hirst that it is best to repair the cervix forty-eight hours after labor, and that every woman should be subjected to three examinations after labor, viz.: The first within forty-eight hours to detect the injuries of childbirth. The second, before she leaves her room, to determine the position of the uterus. The third at the end of the puerperium, six weeks after labor, to observe the condition of all the pelvic organs and structures of the abdominal wall, the coccyx, and the position of the kidneys. The author has made it a practice to examine the patient for the second time before she leaves her bed. There is less danger, it would seem, of pelvic inflammation, of puerperal infection by consistently repairing all lacerations of the cervix and vaginal tract, when done by surgically clean hands, than by leaving these conditions to take care of themselves, especially as parturient women are even more liable to infection through vaginal lacerations than by way of the endometrium.

## GENITO-URINARY AND SKIN DISEASES.

**Localized Ichthyosis.**—The patient was a soldier, twenty-one years of age, who, as far as he can remember, always suffered from a symmetrical disposed eruption of a scaly appearance. Anamnesis otherwise, as well as family history good. The skin under the axillæ, in the substernal regions, around the umbilicus, on the buttocks, and on the groins, is covered with an eruption in the form of symmetrically disposed, distinct spots, covered with grayish-white scales that cannot be removed mechanically, and that feel rough to the touch; the spots are of variable size. The axillary spaces are partially covered with a thick stratum of scales, and the same to a greater or lesser extent is seen in the other above-mentioned localities. Examination of the nervous system developed nothing abnormal outside of a moderate dermographism. The clinical feature of the case, according to Znamensky (Roussky Vratch, No. 22, 1903), lies in the localization of the eruption, which is usually described as affecting the entire body, also in the remarkable symmetry of disposition of the spots on either half of the body. Treatment proved quite unavailable, so much so that the patient as one suffering from an incurable affection was dismissed from military service.

## NEUROLOGY.

**Relation of Neuralgic Headaches to Storms.**—A unique research in connection with this subject has been made by S. Weir Mitchell (Am. Med., June 27, 1903), who presents some very interesting observations in this little understood field. The originating causes of hemicrania are as yet unknown. He asserts that eye-strains are rarely the primary trouble, but they may add to the number and exaggerate the force of the attacks. Fatigue, worry, etc., have a certain influence, and atmospheric conditions have a potent share. He has observed this in a number of instances and reports in detail the history of one case, in which a record of the attacks was kept for seven years. The pain curve was seen to follow the storm curve for that period. Electric storms were not among those which exerted any influence. March and April were the worst months and October and February the best. Nothing definite can, of course, be based upon these data and the author suggests that further observations be made by recording the dates of attacks in afflicted individuals for a period of two years and comparing them with the storm curve for the locality for the same time.

## HISTOLOGY, PATHOLOGY, BACTERIOLOGY.

**Cysts of the Peritoneum Covering the Fallopian Tubes.**—The frequency with which these small cysts are met with must be familiar to all those who work in gynecology and pathology, remarks T. G. Dickson (Am. Jour. of Obstet., June, 1903). They are practically always con-commitant with neoplasms of the generative organs, or the more serious inflammatory diseases of the tubes. They seem to be found most frequently with myomata of the uterus, and salpingitis. Because of their benignity and small size, they are incapable of producing clinical symptoms. As regards their naked-eye appearances, these cysts are occasionally single; more often, however, they are multiple. They vary in size from those which are not visible to the unaided eye to those which are four or more millemeters in diameter. Their location is most often on the anterior and upper surface of the tube. Still they are not infrequently found in other locations. The peritoneum covering the ampulla of the tube contains them most frequently. They are spherical or lenticular in shape, containing a clear or opalescent fluid, and, in tubes without marked perisalpingitis, can be moved freely over the musculature with the peritoneum. They are variously considered as springing from congenital anlage, derived from existing lymphatics, or due to peritoneal inclusions. The author considers that with the character of the cell-lining, such as they have, they come from three sources, namely, the mesothelium in the peritoneum, the endothelium of a blood-vessel, or the endothelium lining lymph-spaces. An origin from blood-vessels seems unlikely, because of the absence of blood in the cysts, and also on account of the absence of elastic tissue in the cyst wall. In the writer's opinion they are dilated lymph-spaces, and are associated with those diseases of the tube and neoplasms of the generative organs which are capable of interfering with the free circulation of the lymph in the tubal peritoneum.

## THERAPEUTICS.

**Action of Somnoform.**—This is the commercial name of a new anesthetic containing ethyl chloride 65 per cent., methyl chloride 30 per cent., ethyl bromide 5 per cent. It has been very largely used in France for producing anesthesia for minor operations. Sydney W. Cole (Brit. Med. Jour., June 20, 1903) reports a series of exhaustive experiments, made at the physiological laboratory, Cambridge, from which he deduces the following conclusions: (1) The chief danger attending the use of this mixture is that it may paralyze respiration. Most careful watch, therefore, must be kept. (2) Owing to the depression or paralysis of the peripheral endings of the cardio-inhibitory fibers and the comparative slight action on the heart itself there is no danger of heart failure, provided respiration has not yet ceased. (3) After cessation of the respiratory movements it is easy to restore the animal by artificial respiration. The author thinks that the paralysis of the cardio-inhibitory fibers by ethyl bromide renders that drug a very valuable anesthetic. Embley has shown that the sudden deaths which sometimes occur during chloroform narcosis are due to inhibition of the heart by stimulation of the cardio-inhibitory center. This is usually seen only in the early stages of chloroform administration; the danger passing off when the medullary centers are exhausted. This suggests the advisability of combining ethyl bromide with chloroform. If in anesthesia produced by ethyl bromide the vagi are paralyzed, chloroform would then be deprived of one of its greatest dangers. It might be possible to get past the stage of excitement with the bromide and, after reaching medullary depression, to maintain anesthesia by chloroform alone, the bromide being stopped because of its depressing effects on respiration.

**The Further Use of Bacterial Vaccines.**—It will not be so very long before the surgeon, who, after all, is a sort of executive slave to the internist, is put on the shelf altogether. A. E. Wright (Brit. Med. Jour., May 9, 1903) looks forward most hopefully to the time when vaccines shall be so perfected as to immunize human beings against the colon bacillus, to say nothing of the staphylo- and streptococcus. Without the ravages of these groups, the surgeon's hand would indeed be stayed. The high standing of the author, as well as the prominence given his paper by the *British Medical Journal*, is warrant for a close observation of his suggestions and conclusions. He says "The colon bacillus, even if we consider it quite apart from its near congeners, the dysentery bacillus, the Gaertner bacillus and the typhoid bacillus, all of which, like the colon bacillus, affect the lower part of the gut. The rôle they play in internal surgery is kin to that of the staphylococcus externally. The gravity of the local process is infinitely graver, first, because of the importance of the organs involved; secondly, from the impossibility of applying antiseptics safely, and thirdly, from the very grave nature of the surgical measures which must be necessary in the event of serious infection." Cholelithiasis is, no doubt, the most important—always excepting appendicitis—of the ills directly attributable to the colon bacillus. Cystitis, meningitis, endometritis, mastoiditis and arthritis are all considered in turn. It is seen that while the results are not by any means brilliant there is enough of encouragement to keep interest in this matter of prophylactic medicine at a high pitch. Progress can only be made if the existence of the negative and positive phase is noted and an effort made to find more exact data upon which to base a recognition of a higher base line of immunity. Until this effort is successful the vaccines cannot be constantly brought to their highest point of efficiency.

**Practical Experiments in the Treatment of Anemic Conditions.**—A series of practical tests have been made with the ferruginous preparation known as Peptomangan (Gude) in other conditions beside chlorosis and anemia, for which it has been particularly recommended. In all diseases attended with weakness and exhaustion, F. Euler Rolle (Wiener klin. Rundschau, March 29, 1903) found that it caused marked improvement and also maintained to some extent the nutrition of the patient, by reason of the peptone which it contains. One series of cases included tabes with gastric crises, vomiting of pregnancy, cancer of the esophagus, diabetes mellitus, arthritis and uric acid diathesis, and leucemia. In all of these cases the improvement could be demonstrated clinically by determinations of the body-weight, by the condition of the gastro-intestinal tract, and by microscopical examination of the blood. It is known that most ferruginous preparations on the market consist of albuminous material held in solution by an excessive amount of caustic soda, thus neutralizing the gastric juice, or through their decomposition the irritating chloride of iron is produced. Others represent peptone combinations containing an excessive amount of mineral acids and, therefore, are precipitated by the alkaline intestinal secretions and rendered less assimilable. Pepto-mangan does not seem to share these disadvantages and owing to the presence of manganese, is an excellent carrier of oxygen. No unpleasant after-effects have ever been observed.

**The Use of Arsenic in Chorea.**—The value of arsenic in chorea of the infectious or rheumatic type is questioned by H. Roeder (Fortsch. d. Med., July 1, 1903). He made some very careful clinical observations in a number of children who received arsenic in the form of arsenical mineral waters or Fowler's solution, in increasing dosage up to 12 drops t.i.d. In most of the cases there was found after the twelfth day, a sudden or a gradual rise of temperature and an accelerated pulse. There was also noted systolic murmurs over the apex, stenocardia or arhythmia, and increase in the area of cardiac dulness. The subjective symptoms also grew worse and there was apt to be a recurrence of the previous rheumatic conditions. Digestive disturbances resembling the typhoid state were often present. In most cases, as soon as the drug was stopped, the patient improved, but in the severe cases permanent harm resulted. The author states that in the neuropathic type of chorea, he has not observed these detrimental effects. He is unable to explain the toxic effects of the arsenic in the one case and its absence in the other.

**Veronal, a New Hypnotic.**—This new drug, first introduced, a short time ago, by E. Fischer and v. Mering, has since been tried by a number of men, the last report being by F. Lotsch, of the 'Charite' in Berlin (Fortschr. d. Med., July 1, 1903). He employed the drug in 30 cases of various types and found it of especial value in insomnia which was not due to pain. The effect was prompt, a natural sleep coming on usually within half an hour, and no unpleasant after-effects were observed on awakening. In doses varying from 0.25 to 1.0 gram, it may be given for a considerable period. It is, relatively speaking, non-toxic, is readily soluble and almost tasteless. It has no effect on the heart and kidneys, and in cardiac cases, with poor compensation it semed to be of especial value. The cost is also somewhat less than that of the other newer hypnotics.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, AUGUST 1, 1903.

## A NEW POINT IN MEDICAL JURISPRUDENCE.

It has usually been held in the courts at least in the few cases that have come to trial, that an amputated limb or a removed tumor, is the property of the patient and that he has the right either to dispose of it as an anatomical or pathological specimen—or, as in the case of Jackson, to have it buried with full eccleciastical rites. The case of "*Palear versus Jenkins*," however, that is now coming to trial in Chicago, presents a different point, that smacks rather of equity than law, and which seems to give more grounds for damages than for a simple charge of theft.

Custom is always a difficult thing to overcome, and habits when long continued are hard to break. We all grow used to conditions that are continuous, and are often much more disturbed by their sudden cessation than we were in their occurrence. Thus the miller does not heed the noise of his wheel while it is in motion, and nothing rouses the captain of a vessel from his sleep so quickly as the stopping of the machinery.

All this makes it trying to a person who is suddenly confronted by a radical change in what he is thoroughly accustomed to, and this change becomes almost unbearable when it is associated with personal loss, or a feeling of injury. This, too, is more accentuated when the wrong is inflicted by one who has been trusted, and who has been sufficiently intimate to have been a companion in unusual and singular experiences.

It seems that Mr. Kasmar Palear, of Wade St., Chicago, has been not only a victim of misplaced confidence and reptiles, but has also had the bad luck of becoming a most striking illustration of "Man's inhumanity to man." Several years ago Mr. Palear swallowed a lizard, still in its tender youth, and has ever since nourished it, until it can be fairly said to be a second nature to his own. This act of hospitality has, it is true, been hidden from the world. But deep down in his vitals, Kasmar has been conscious of it, and his feelings have been constantly stirred with the warmth and glow of a knowledge of benefits bestowed.

Only a few days ago this Chicago landlord—a very host within himself—parted suddenly and in anger with his tenant, in the presence of a friend. This appears to have been a certain Mr. Jenkins who, up to this time it seems, had played the rôle of Boswell to his Johnson and occupied the position that Hennessy now fills for Mr. Dooley. What the cause of the rupture was we cannot say. It may have been one of the cases, in which out of the fulness of the heart the mouth speaketh: or he may have been a truant lizard that thought his home a cage. At all events, he appeared on the scene as green as the leaves of the forest in summer, and dotted with spots as unchangeable as those of the leopard. Poor Palear was stupefied, for he was in the position of the man who with honorable intentions had long corresponded with the object of his affections, without a personal interview, and suddenly discovers that he had builded better than he knew. But if he was dazed his quandam friend was not, and off he started in pursuit.

It was, it seems, a case of up Jenkins and down lizard from the start. At last he captured the errant reptile, and now he claims it for his own. To this Mr. Palear will not agree, and in a sworn statement he declares that he has been robbed of what has long been an integral part of his personal estate. He claims also that it has a cash equivalent, and that he has been feloniously deprived of ten inches of lizard, valued at twenty dollars per inch, and that Mr. Jenkins having been present at the first interview, is fully cognizant of these facts. To these allegations Mr. Jenkins offers no demurrer, but claims the thing is his, by right of capture and his own strength of nerve.

What the judge will rule is hard to say. The legal points are delicate and involved, as the statutes on landlord and tenant do not apply, the lizard having vacated voluntarily. As yet Mr. Palear has made no demand for unpaid rent. Neither has Mr. Jenkins sufficient authority to class the lizard's occupation as eminent—though it was certainly extraordinary—domain.

As to our sympathies, they are with Mr. Palear—*he had it first.*

## KIDNEY DISEASE AND INSANITY.

Studies of the excretory organs and excretory functions are gradually bringing to light corroborative evidence of the autotoxic theory of insanity. Unfortunately, such studies have, for the most part, been limited to some observations on the kidneys and the urine. The unusually frequent association of kidney disease with the various forms of insanity has been repeatedly shown and statistically proven during the past few years. If the kidneys are called upon to excrete an increased quantity of indican and the sulphates in some forms of insanity (Hamilton and Turner), or an increased amount of xanthin compounds or of uric acid (Haig), or even an occasional poison like acetone (Wagner), demands are made upon these organs which will ultimately show themselves in well-marked kidney lesions.

The observations of Bristowe on paresis, in which he found a gross kidney lesion in 88 per cent. of his cases; Beadles' figures for 150 post mortems in insanity in general, 70.6 per cent., and Prout's figures for a like number of autopsies, 69 per cent., are fairly well known. The extreme frequency of kidney lesions in paresis has been especially noted by both Bristowe and Prout.

Beadles compared his figures with some statistics from St. Bartholomew's Hospital. In 194 deaths from all causes in persons over thirty years of age, 48 per cent. showed a gross kidney lesion at autopsy. If the cases of insanity under thirty years of age were excluded from the figures given by Beadles and Prout, the percentage of kidney lesions in the remainder of their cases would be much higher.

Perry has recently published some observations on this subject and has carried his investigations a step further than the autopsy table (Transactions of the Medical Association of Georgia). He finds evidences of nephritis in 33.7 per cent. of the cases admitted to the Georgia State Sanitarium and in 70 autopsies the percentage showing kidney lesions was 85.5 per cent.

Unfortunately there is no tabulation of the ages of the patients in either the urinalyses on admission or the autopsies. The author found casts in the urine, when albumin was absent, in 19.1 per cent. of the cases examined on admission. He considers this together with the very great frequency of the occurrence of cylindroids, as evidence of long standing renal irritation. Another fact of much importance pointed out by this author is the extreme frequency of arteriosclerosis (88.5 per cent.). Here again we miss the tabulation of the facts, according to the ages of the patients; the author states its occurrence, however, in a number of cases under thirty years of age.

All these changes are probably of secondary rather than of primary origin, but their importance is of the first rank. Cardiac hypertrophy would suggest itself as one of the first sequences of changes of this character, but no adequate statistics are at hand in support of this theory. Some work has been done on valvular heart lesions in the insane, but thus far no systematic efforts at determining the cardiac area in all cases of insanity have been made. The great therapeutic importance of determining this point is obvious. The various organs of the body have received too little attention at the hands of both asylum clinicians and pathologists, the tendency being to skip hurriedly over the internal organs and to spend much valuable time on the brain, an organ our knowledge of the physiology of which is so limited that no investigations except those of the most painstaking and exhaustive type can be of any value whatever. Unfortunately, the requisite knowledge of the undertaking of work of this character and the opportunities for acquiring it, are rather limited with us.

Some fields of investigation are, however, directly accessible and would well repay investigation. The liver, the lungs, the skin and blood states in the insane in general, have been almost entirely neglected in the impatient haste to get at the brain with faulty methods and a technic more faulty still. If the autotoxic theory of insanity is correct, the various organs of the body having any major part in the processes of elimination should be investigated first for corroborative evidence of it.

Perhaps no research would bring larger returns in the shape of practical discoveries than a systematic and extensively conducted investigation of the changes that take place in the blood and the secretions and excretions of these patients.

### THE UNIVERSITY IN MEDICAL EDUCATION.

One of the few opportunities out of the pulpit that is afforded to preach ethics and high standards, comes to men eminent in their profession when they are invited to address a graduating class at a University commencement. Doubtless the best idea of a nation's ideals and aspirations can be obtained from such addresses, and a better appreciation of educational values has been brought about by the long established custom.

The annual address to the graduating class of the Yale Medical School given by Dr. Henry M. Hurd of Johns Hopkins Hospital, and published in *Science*, contains suggestions that are pertinent to all interested in medicine.

After tracing briefly the circumstances of medical education in America, he shows the two methods by which different colleges and institutions approach the question "How shall medical education be studied." On one hand there is the opportunity given to the student to begin his medical work in the third year of college, and to combine his studies for his bachelor and medical degree. On the other hand there is the tendency to divorce the medical question from the college course and to pursue the latter independently. While the first mentioned is the more practical method, and the one most likely to be in vogue, the latter tends more to general culture.

Dr. Hurd maintains that the present requirements for medical education have become so extensive and exacting, that schools which have hitherto been maintained as commercial ventures, and for the private gain of their owners, can no longer be profitable if they honestly seek to do their duty towards the student. Such schools although making the most praiseworthy efforts to fit men to be doctors, do little for the science of medicine. He holds that the present situation demands that schools connected with universities shall perceive the need of the student, and protect him from imposition by affording him instruction of a high standard, and that the university should set the standard. The country suffers from too many imperfectly educated men. The university is alone competent to limit the production and to improve the quality.

The intensely practical nature of the studies of a physician are by no means undervalued by Dr. Hurd, but he holds that in view of the tremendous scientific achievements of the last half century, and the possibilities of still more brilliant work, that the medical school needs every advantage that the university can afford.

## ECHOES AND NEWS.

### NEW YORK.

**Prevalence of Trachoma.**—Dr. John C. Lester, assistant surgeon of the New York Eye and Ear Infirmary is authority for the statement that there are at least 25,000 cases of trachoma in this city. The disease is common among foreigners and they are largely responsible for its spreading.

**Board of Health Clinic.**—Plans have been filed at the Bureau of Buildings for a one-story brick clinic, 25x80, to be erected at No. 965 Sixth avenue, for the purpose of examination of patients thought to have contagious diseases. There will be an X-ray room, throat examination room, drug store, two clinics, and a general examination and waiting room.

**Bellevue and Summer School of Philanthropy.**—Fifty members of the Summer School of Philanthropy paid a visit to Bellevue Hospital last week. They spent some time in the office of Dr. William Mabon, the superintendent, where the workings of the hospital were explained to them. In company with one of the staff doctors and a nurse they visited all the departments.

**Cost of Enforcing Dog Ordinance.**—The Aldermen, upon receiving from Mayor Low a statement to the effect that President Haines of the Society for the Prevention of Cruelty to Animals wanted $76,800 a year to carry out the recently enacted dog-muzzling ordinance and would need $26,000 of it immediately in order to enforce the regulation during the hot weather, referred the matter for an early report to the Committee on Laws and Legislation.

### PHILADELPHIA.

**Dr. Stelwagon Honored.**—Dr. Henry W. Stelwagon, Clinical Professor of Dermatology at Jefferson Medical College, has been elected to honorary membership in the National Dermatological Society of France.

**Baby Directory to Cover Entire City.**—The Bureau of Health has decided to apply the system of visiting and registering babies under one year old to the entire city instead of to the district south of Spruce and east of Broad street, as originally planned. The entire force of fifty District Physicians have received instructions regarding the work which will begin as soon as the registry cards and circulars are ready. It is considered quite probable that the present force of fifty physicians and sixty nurses may have to be increased before the end of the summer.

**Mothers to be Instructed in Care of Children.**—Plans to give a series of plain talks to mothers on the care of babies are being perfected by Dr. Martin, Director of the Department of Health. Nine physicians have volunteered their service to carry out the work. The lectures will be held under the auspices of various church guilds, day nurseries, the College Settlement and the Pennsylvania Congress of Mothers. All these centers will arrange localities and fix the date for the physicians to give their lectures. A circular outlining the topics to be treated by the physicians in these talks has been prepared by Dr. Martin. Special efforts will be made to reach the mothers who do not understand English.

**The Municipal Hospital Affair.**—Since the appointment of the Director of Health and Charities there have been comments upon the frequent appearance of newspaper interviews regarding the work of that department. While the great majority

of these interviews have been entirely innocuous, it was thought by the more conservative that many of the criticisms (even though they were just) on existing affairs, as well as plans for the future, should be given less publicity. As a logical outcome of this newspaper campaign there has appeared an undesirable controversy regarding the management of the Municipal Hospital. As to whether the severe strictures upon Dr. Welch's management of the hospital made by Dr. Martin are deserved we are not at present concerned. Dr. Martin undoubtedly found at the Municipal hospital many things that were not as they should be. Some person or persons are responsible. Whoever he or they may be, Dr. Welch can hardly be blamed for replying to the following which is part of what was quoted in one of the leading daily papers as coming from Dr. Martin regarding the hospital: "I cannot understand how the institution could have been conducted in the past to bring about such a deplorable condition both as regards equipment and organization. People suffering from contagious diseases are compelled to go there, and it is not too much to say that they run great risks of not only failing to be cured, but of contracting other diseases from neighboring patients. I am astounded at the gross negligence which has characterized the management of the Municipal Hospital. The equipment and the discipline are almost a disgrace to the city, and will need the concerted attention of the Health Department to bring the institution to the condition in which it ought to be for the reception of patients. Dr. Welch is undoubtedly responsible to some extent, but just how far I do not know. We are making a very searching investigation to determine who is to blame. There is no fault to be attached to the Councilmen, for they have had no appropriation measures submitted to them for consideration. The whole matter has arisen from the neglect of the management of the institution to apply for aid from the city in the proper and customary way. And this neglect is typical of the general conduct of the hospital in the past. It passes comprehension how men to whom its affairs have been intrusted could allow it to become so run down." On the other hand, the statement that Dr. Martin's accusations are prompted by the outcome of last year's factional contest in the County Medical Society over the endorsement of a candidate for President of the Medical Society of Pennsylvania, is unworthy of its originator. The members of the Medical profession in Philadelphia will welcome needed improvements in any service that comes under the jurisdiction of the Director of Health and Charities and stand ready in every way to aid the Department, but they deplore the present publicity of criticisms emanating therefrom.

**Smallpox and Red Light.**—The suggestion to combat smallpox with the red light treatment has been abandoned by the health authorities in Philadelphia after consideration. It is an old idea, centuries old in fact, and is said to have been put in practice by the Arabians. Prince John, a son of one of the Edwards, was treated by this system. Everything was red. He was even given mulberry wine on account of its color. The theory is that daylight, and especially the chemical rays, have an injurious effect on smallpox patients, inasmuch as the strong rays of the sun cause inflammation or sunburn in healthy persons. But experiments at the Municipal Hospital in Philadelphia did not confirm this theory. Only negative results were obtained there, as in other hospitals where the treatment has been tried. In Philadelphia the room used was painted red and had red glass windows. Red curtains obscured the doors and red globes covered the gas jets. The patients were neither harmed nor benefited. Within the last year a red light ward for the treatment of smallpox was constructed in the hospital in Indianapolis. One hundred and forty victims were put in this new ward and by way of experiment the same number of cases was placed in the ordinary ward. The results showed that the red light treatment was neither baneful nor beneficial, and the treatment was abandoned. In Norway and Belgium the red light treatment for smallpox is used extensively and they contend with success in reducing the mortality list. But it is well to remember that in those countries vaccination is the universal practice. Reason, as well as tests, disprove the theory. Diffuse rays of light are not capable of inflaming the skin. Only the strong light of the sun does that. The negro has the best possible protection in his skin against the action of the rays of the sun, and yet negroes have more occasion to dread smallpox than white people have. So, too, if the actinic rays of the sun aggravate the eruption of smallpox, then the smallpox in summer ought to be worse than the smallpox in the winter. Yet smallpox is usually more severe and more abundant in winter than in summer.

## CHICAGO.

**Fewer Contagious Diseases.**—Only 57 cases of the contagious diseases—diphtheria, measles, scarlet fever, smallpox, etc., were reported during the week ending July 18th. This is the lowest number since September, 1901. In the corresponding week last year there were more than twice as many—119—and the 34 cases of diphtheria and 14 cases of scarlet fever reported this week are one-third and one-half less than the respective number reported during the previous week. Measles, which has been epidemic for many months, is fast disappearing, as also is smallpox, the solitary reported case of which was that of an unvaccinated infant of 6 months.

**Decrease in Infant Mortality.**—During the week ended July 18th there were nine fewer deaths in children under one year of age than the week before, and 25 fewer than the corresponding week of last July. A more marked result is seen in the fewer deaths among the aged, those over 60 years. This decrease in mortality in the two extremes of age is due to the "summer resort" weather Chicago has been having.

**Personal.**—Dr. N. Senn is taking his vacation in the West, visiting Rock Springs, Wyoming; the Yellowstone Park, and from there he will go to the Yosemite Valley.

**Mortality Comparison.**—During the first six months of this year a total of 15,201 deaths from all causes were reported, giving an annual death rate of 16.24 per one thousand. This is an increase of 3,103 deaths over those reported for the first six months of 1902, and an increase of 18.5 per cent. in the annual rate in proportion to population. Of the causes of death showing the greatest rate of increase were typhoid fever, 154 per cent.; scarlet fever, 147 per cent.; measles, 136 per cent.; pneumonia, 60 per cent.; Bright's disease, 58 per cent.; acute intestinal diseases, 29 per cent.; suicide, 24 per cent.; consumption, 17 per cent.; heart diseases, 14 per cent. Pneumonia causes 3,133 deaths in these six months, as against 1,961 in the first six months of 1902, and consumption 1,561 and 1,325, respectively.

## GENERAL.

**Appointment of Professor Kraepelin.**—Dr. Emil Kraepelin, professor of psychiatry at Heidelberg, has been called to Munich.

**Library of Professor Schede.**—The library of the late Professor Max Schede, formerly director of the surgical clinic of the University of Bonn, has been presented to the clinic by his widow.

**Retirement of Prof. Huppert.**—Dr. Carl Hugo Huppert, professor of medical chemistry at the German University of Prague, will retire at the end of the present semester.

**Appointment of Dr. Page May.**—At University College, London, Dr. Page May has been appointed lecturer on the physiology of the nervous system.

**McGill Appointments.**—The following appointments have been made at McGill University: Dr. J. G. McCarthy, to be assistant professor of anatomy; Dr. J. T. Halsey, to be assistant professor of pharmacology and therapeutics; Dr. R. A. Kerry, to be lecturer in pharmacology and therapeutics; Dr. S. Ridley Mackenzie, to be lecturer in clinical surgery; Dr. John McCrae, to be lecturer in pathology; Dr. D. A. Shirres, to be lecturer in neuropathology; Dr. D. D. McTaggart, to be lecturer in medico-legal pathology.

**Gift to McGill University.**—The late James Cooper gave $60,000 to form a fund from which to pay the cost of establishing, in the medical faculty of McGill University, a chair for the teaching and study of internal medicine, on lines to be determined by the medical faculty itself. This will be known as the Cooper endowment fund, and will be paid two years after the death of the testator.

**Medical Department, University of Texas.**—Since the publication of the last catalogue a private benefaction has been placed in the hands of the Regents in the form of a five-year endowment for University Hall. Following the purpose of this donation and conforming with the original purpose of the donor of the Hall the Regents have determined to remove from the building the University Hall Dining Club and to devote the entire hall to the uses of the women students. By this arrangement the hall will be under the control of a matron appointed by the Board of Regents; and the rooms, with the light, heat, water and service will be furnished at a low rental to the women students of the institution who may elect to take up residence in the building. The present Board of Lady Managers is continued as an advisory and visiting board; but all questions of management are assumed by the authorities of the school. It is felt that with the improvements thus made possible in the material and general conduct of the hall it will prove an admirable home for the women who are in attendance in the schools of medicine and pharmacy. In addition there have been provided two scholarships, by the Woman's Club of San Antonio, granting to the holders the sum of two hundred and forty and two hundred dollars, respectively, annually; these are to be given to those two women in the medical class who after the freshman year shall have attained the highest general averages of proficiency in their studies.

**Trypanosoma, the Tsetse Fly and the Sleeping Sickness.**—A highly interesting and important pamphlet has just been issued by Prof. Ray Lankester and his assistants of the British Natural History Museum in relation to the suspected connection between the tsetse fly and the sleeping sickness which has been making such havoc in certain parts of southern and western Africa. Col. Bruce discovered that the tsetse fly produces the death of horses and cattle by introducing into the blood of its victims a minute parasite, and in the early part of this year Dr. Castellani, a member of the Royal Society Commission, sent to Uganda to investigate the sleeping sickness, found this parasite in the cerebro-spinal fluid of nearly 70 per cent. of the cases of sleeping sickness examined for this purpose by him at Entebbe in Uganda. Until recently, it was supposed that the tsetse fly was inseparable from the African buffalo, and could only exist in districts inhabited by that animal. But this theory is now much doubted. Sir Charles Eliot, Commissioner and Consul-General for British East Africa, is convinced that the buffalo cannot be the only host of the parasite which the tsetse fly introduces into the blood of domestic animals. Commissioner Sir Alfred Sharpe declares that the tsetse flies appear to depend upon wild game for their existence, as he had never found them where game was nonexistent, but does not think that they are in any way especially dependent upon buffalo. Mr. F. J. Jackson, Deputy Commissioner for British East Africa, is firmly of the opinion that in East Africa the existence of the tsetse fly was never in any way more closely connected with buffalo than with any other species of game, and expresses his conviction that the tsetse is, like the mosquito, only a bloodsucker by predilection.

**Our Chaotic Food-laws.**—Under this caption the New York *Evening Post* very soundly says: Professor Wiley's report on his "poison-squad" experiments is not to be made public, it seems, until October. But recently, in an address at St. Paul, he made it pretty plain that they have only confirmed the position of the German Government—namely, that the use of food preservatives is harmful to health. Some preservatives, at any rate, Professor Wiley admits to be "deleterious," and he urges legislation, both national and State, to prevent food adulteration and the use of pernicious preservatives. The safeguards provided by the new law against impure or falsely labelled foods and wines imported from abroad are, indeed, in striking contrast with the inadequate and confusing statutes which are supposed to protect us from adulterated and injurious food products at home. By the act which went into effect on July 1, the Secretary of Agriculture is clothed with authority to confiscate any shipments of objectionable foreign foods at the Custom House, although, in the Attorney-General's opinion, his jurisdiction does not apply to such as are imported in the pure state, and adulterated or falsely branded afterwards. It is a law which, wisely and thoroughly enforced, should shield effectually the customers of the "fancy grocery store." Meanwhile, how do we stand with reference to domestic products, compared with which imported food is trifling in quantity? Many of the States, especially in the East, have food laws. Some have good laws, earnestly enforced; some good laws with no machinery to carry them out; some lax laws, and some no laws at all. There is no uniformity except in so far as the States have copied one another's statutes. It is a remark of Professor Wiley, Chief of the Department of Agriculture's Bureau of Chemistry, that a food manufacturer requires the services of a lawyer to see that the laws of the different States are complied with merely in the matter of printing labels. Take the case of a jam or a jelly containing glucose in place of cane sugar: in Ohio or Massachusetts its label must show the exact proportion of each ingredient ac-

cording to analysis. In Minnesota, the label "adulterated mixture" must be affixed to this same jam, in Pennsylvania "compound," and in Illinois "imitation." In this State, the law can be complied with by the declaration in fine type around the edge of the label in the guise of an ornamental border that the preserve "contains a small amount of corn syrup [glucose] to prevent crystallization." It is often illegal to sell in one State a product which was put up in strict conformity with the law of its next neighbor.

Toward remedying this chaotic condition, Congress has done almost nothing. The Hepburn National Pure Food bill which passed the House last winter, reached the Senate late in the session and died there. At the demand of the dairy interests, however, a discriminating tax was placed on oleomargarine colored as butter is colored, though this is a perfectly wholesome article of food. Protection against one form of deception is also afforded by the act which makes it a misdemeanor to introduce into any State a dairy or food product falsely labelled as to the locality of its production. This law was introduced by Representative Sherman of this State, and was designed especially to prevent the branding of cheeses produced elsewhere, as the famous "New York full cream cheese." So far as the national law is concerned, it makes no difference whether the product is really a full cream cheese, provided it were made in New York. The fortified wines, then, the borax-preserved sausage, the reimported cottonseed oil, masquerading in the guise of "pure olive," and the French peas colored with copper, Congress is resolved to keep from our tables. It does not concern itself with the "pure maple sugar" which never saw a maple tree, the "comb honey" made of paraffin and the indispensable glucose, the low-grade flour whitened with alum, the dilute acetic acid which passes as vinegar, the red wood and charred peanut shells in spice boxes, or the strawberry jam made of flavored and tinted glucose and gelatin mixed with timothy seed, all of which are domestic products. The workingman may be sure that his *petit pois* and cognac are all that could be desired, however much doubt there may be as to his bread and salt. The consumer of impure food is cheated even when he is not poisoned. If he wishes to economize by using oleo or the euphemistic "corn syrup" on his table, that is his own concern, but it is unfair both to manufacturers and buyers if these things can be put on the market as maple sugar and butter. If all the States had good food laws and enforced them, a national law might be unnecessary. As it is, one of the chief difficulties of city health departments is to hunt down the impure food products brought in from other localities. It is comparatively easy to hold the manufacturers to account, and a single rigid inspection of a factory may result in holding back from the market large quantities of deleterious food products. It is a very different matter to seize a half-dozen packages of this same food at a corner grocery store, and then throw the responsibility back upon the maker who may have violated no law of his own State. The national statute would not only stop shipments of the harmful commodities from one State to another, but also furnish a model for those States which have not yet passed food laws of their own.

**Explosive Bacterial Products.**—The comparatively new method of purifying sewage by encouraging the growth of certain forms of bacteria in it, while it is retained in closed tanks, has recently led to several serious and novel accidents in England. Certain inflammable and explosive gases are formed during the closed tank stage. These have in three instances, viz., at Exeter, Walton-on-Naze and at Sheringham, exploded with more or less serious results. At Sheringham the explosion killed three persons and seriously injured several others.

**Obituary.**—Dr. John Evans Walker, a prominent physician of this country, well known throughout the South and in New York city, died July 24th of hemorrhage of the brain. At one time he was the immigration medical inspector at Ellis Island, New York.

Dr. Milo Hotchkiss Jones, son of Dr. Leander P. Jones, and assistant to his father, the health officer of Greenwich, Conn., died last Monday of a fever contracted two weeks ago while attending to his duties. He was only twenty-eight years old. He was graduated from the Yale University medical department and practised for a year in Bellevue Hospital, this city.

## OBITUARY.

### DONALD MACLEAN, M.D., LL.D.

Dr. Donald Maclean, ex-president of the American Medical Association, and until recent years one of the most widely known surgeons in the Middle West, died at his home in Detroit, Michigan, July 24th. He was born at Seymour, Canada, December 4, 1839, of Scotch parents, his father, a man of brilliant attainments, in spite of his total blindness almost from infancy, being an eminent lawyer and leader of the Canadian Bar. At the age of six, young Maclean was sent to a famous school for boys at Edinburgh, where he remained six years. When sixteen years old he matriculated at Queen's College, Kingston, Ontario, from which institution he was graduated in 1858 with the degree of Master of Arts. During the summer of the same year he returned to Edinburgh and began his medical studies at its University, receiving his degree of Doctor of Medicine and his license from the Royal College of Surgeons, Edinburgh, August 1, 1862.

During the last year of his medical course, and throughout his subsequent hospital service, he was closely associated with the celebrated Professor Symes, and to this surgeon's influence and teaching he always attributed his own success in surgical practice in after years. Many years after graduation he edited and published, largely at his own expense, an Americanized form of his preceptor's "Principles of Surgery," which, however, never attained great popularity as a text-book in this country.

In January, 1863, Dr. Maclean returned to America, and immediately entered the United States Army as acting-assistant surgeon. In 1864 he resigned in order to accept the chair of clinical surgery in the Royal College of Physicians and Surgeons at Kingston, Ontario, which position he retained until 1869. In 1872 he was appointed professor of surgery at the University of Michigan at Ann Arbor, where he remained seventeen years. In 1889 he severed his connection with the University and removed to Detroit, where he quickly built up a very large practice. In 1893 the degree of LL.D. was conferred upon him by Queen's College, Kingston, and in 1894, at the San Francisco meeting, he was elected president of the American Medical Association, the duties of which position he

discharged with dignity and discretion. On the breaking out of the war with Spain he accepted a commission as chief surgeon with the rank of major and was assigned to duty at Fortress Monroe, thus reentering the service of the United States after an interval of thirty-four years.

During the past two years his health had gradually failed and he had entirely given up active practice. The immediate cause of his death was gastro-enteritis.

It falls to the lot of but few men to possess the friendship and esteem of those with whom he came in contact, in like measure with Dr. Maclean. Ever going out of his way to lend a helping hand to those less successful in the battle of life than himself, his purse always open, during his active career he was the embodiment of all that is noblest in the life of a physician. Tenacious of his opinions, like all Scotchmen, a master of argument, yet he was unequaled in courtesy, unvarying in his inability to cause pain to the most sensitive. He loved well and, like all strong personalities, he hated well, but few of those who were most closely associated with him and who knew him best ever plumbed with certainty the depths of his feelings. Oftentimes an avowed enemy—an enemy only because of differences in opinion—became his warm friend, unable to withstand the influence of his honest, lovable nature, but never did a friend become his enemy.

## SOCIETY PROCEEDINGS.

### HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

*Regular Monthly Meeting, held May 23, 1903.*

The President, Frank Daniels, M.D., in the Chair.

**Some Medical Features of Life Insurance.**—This was the subject of the paper of the evening by Dr. Augustus S. Knight.

**Heredity and Brevity of Life.**—Dr. Knight said that the occurrence of short-lived families, members of which died at comparatively early ages, was now generally acknowledged as the occurrence of distinct heredity longevity in other families. Hence the necessity for careful gleaning of the family records for life insurance purposes. Certain families seem to have much less resistance to acute and chronic disease, besides their tendency to inherit certain specific diseases. Gout is a question of inheritance largely, and it is well understood that the condition of arteries which predisposes to apoplexy is also inherited.

**Cancer and Life Insurance.**—Very often the existence of cancer in families is denied at the time of medical examination, though subsequent revelations show that it has been present. Malignant disease constitutes the main reason why life insurance for women has never proved a successful feature of the business. While women live longer than men in the general mortality statistics, and while the medical examination ought to secure only the selected lives among women, somehow the mortality statistics of these selected lives were never as favorable to the company as the selected lives of men insured.

**Underweight and Overweight.**—Individuals who are under the normal weight are not favorable subjects for life insurance for two reasons. First, because of their liability to phthisis, and secondly, because of a special tendency to nervous diseases of various kinds. It seems probable that many of the cases of underweight, which later develop phthisis, are really examples of undiscovered tuberculous lesions of the lungs, or cases of latent or partly healed tuberculosis. Persons who are overweight are quite as unfavorable subjects for life insurance. They succumb especially to acute diseases, to surgical operations and to accidents. They have a special liability to heart complications and to apoplexy. Such persons usually eat too much and take very little exercise and thus throw a heavy strain on their heart arteries and eliminating apparatus. The statistics of life insurance companies show that persons who are overweight are especially liable to apoplexy and to heart complications of various kinds, and that in them accumulation of fat around important organs seems to make the general nutrition of low grade vitality, if it is not that the tendency to produce fat is in itself a manifestation of lowered vital resistance.

**Substandard Risks.**—It is easy to understand then that life insurance companies have had to create a class of substandard risks, that is, of lives on which insurance is granted only for definite terms under special conditions and at rates above the ordinary, according to the amount of extra risk involved. When individuals are 25 per cent. above the normal rate, the death-rate from all the causes described is prone to be high, and such cases can only be taken on the substandard basis. Practically all of the tendencies that are known to cause shortening of life, when existent in persons who have no absolute organic disease, come under the same classification.

**Occupation Hygiene.**—In recent years particularly, insurance companies have come to recognize that the moral hazard with regard to life insurance is more important than the added dangers of premature death because of conditions impairing vital resistance that may be found by medical examination. Individuals of immoral habits are proverbially short-lived, and the expression "they go the pace that kills" is literally exemplified by the statistics of life insurance companies. Gamblers, those engaged in the liquor business, and men who make their living by their wits are prone to be in frequent danger of excesses that eventually lead to shortlivedness. Even when bartenders do not use tobacco or liquor they are almost sure to be below the standard in actual expectation of life. Immorality has something to do with this, and the carelessness begotten of late hours, irregular living and the like are other important factors. In deciding the class of risk and the probability of its proving profitable for the company, physicians should take these considerations into account. The question that physicians have to answer with regard to the personal circumstances and the hygienic conditions of life of the patient refer to the moral hazard as well as to any physical risk that may seem to be present.

**Women in Life Insurance.**—According to the census, women on the average live to attain a higher age than men. This is what might be expected from the fact that they are not exposed to so many dangers, are not prone to so many excesses, are not exposed to unsuitable weather conditions. They would seem to be, therefore, eminently suitable risks for life insurance. The selected risks, those, namely, which had passed medical examiners, would seem to be especially likely to be profitable for insurance. Notwithstanding all these facts, the insurance of women has so far proved a constantly losing feature in life insurance. The main reason for this is that the moral hazard is greater in the insurance of women. The whole proposition must be looked at from the standpoint of financial risk. If many women applied for life insurance it would be different, but of the comparatively few who do apply, most are living under circumstances that makes the moral hazard much greater. Men, as a rule, do not consider that their wives should be insured, as they realize that it is the wives and not they who are the proper subjects of ben-

efit by life insurance. The main reason for the failure of the life insurance of women to be a profitable feature would seem to be that women much more frequently have an intuitive premonition of failing health than have men. They are more liable to malignant disease, which carries off so many victims in early middle life. Insurance companies have decided that the insurable interest in the case of women is not more than may be required to pay the expenses of the last illness and the funeral. Of course, where women are wage earners, or where they are active partners in business, there may be good reason for insurance, for the benefit of children or of partners. In these cases the insurable interest in a woman's life is quite as evident as in that of a man, and, taken on the whole, the insurance of such cases has not proven a money-losing departure for the insurance companies.

**Heart Disease in Substandard Risks.**—The existence of a slight heart lesion is the most frequent reason of classifying risks as substandard. Aortic heart disease, as the most frequent forerunner of sudden death, is not considered suitable for insurance, and is always rejected. A condition of mitral stenosis if of no great degree and if unassociated with mitral regurgitation, may be accepted, under special conditions. In the same way a slight amount of mitral regurgitation may be an acceptable risk, provided there has been no signs of any break in compensation at any time, no matter how long before the examination of the subject. The most important features with regard to the acceptability of slight heart cases as risks is the general condition of the applicant, his or her previous history and the question of weight. Any tendency to overweight is considered as a bad sign in those with any heart trouble and usually leads to their rejection.

**Dyspnea and Failing Compensation.**—If there has been at any time a tendency to dyspnea, that is, a marked shortness of breath in going up stairs, then a cardiac case is not acceptable as a life insurance risk. Further signs of dyspnea are incompatible with any prognosis of prolonged life. This is usually the first symptom of a break in the compensation, but other signs may be helpful in determining that the heart muscle has become incompetent for its work, marked tendencies to headache or a lessened amount of urine or nervous irritability of the heart when there is also an organic condition are all symptoms that forbid the assumption of the risk.

**Albuminuria.**—There are many patients suffering from albuminuria, who will live a score or more of years. Life insurance companies have been condemned, but without proper reason, for the rejection of such cases. The trouble is that medical science has so far furnished no distinction that gives any assurance as to the prognosis of cases in which albuminuria is present. The amount of albumin is not enough to decide this, and a trace of it may be the signal for a fatal termination within a few years, while a considerable amount is occasionally present, yet the sufferer may continue in life for a period long enough to make life insurance assumed on him profitable. Over and over again this has been demonstrated by the records of life insurance companies with regard to albuminuria, which have been very faithfully and completely kept in this matter for the twenty years. Many good authorities in clinical medicine are convinced that there exists a functional albuminuria dependent not on some lasting pathological lesion of the kidney, but on some passing condition either in the blood or in the renal secretory cells and without ultimate danger for the patient. Functional albuminuria is not easy to determine, however. More than once traces of albumin that have been attributed to functional albuminuria have proved eventually to be the preliminary signs of beginning Bright's disease, with fatal issue in from three to five years. Insurance companies have decided that unless certain conditions are all present in a case in which albuminuria occurs even intermittently, the risk will not be accepted. These conditions are those which have been found to occur in cases where careful following of the history has shown that the albuminuria continued for many years without any effect upon the general health.

**Conditions of Functional Albuminuria.**—First there must be no family history of Bright's disease. While Bright's disease is not in the strict sense of the word an hereditary affection, there is no doubt that cases of renal degeneration are prone to run in groups in individuals who are closely related to each other. There must be no renal symptoms, that is, the urine must be otherwise normal; there must be no tendency to pain, no irritating condition of the urine itself and no other abnormal constituents. Besides this, the patient must be under forty years of age, must have no bad habits and must never have suffered from any, even the slightest amount of dropsy. The aortic second sound must not be accentuated, and the blood pressure in the general arterial system must not be higher than normal. The specific gravity of the urine must not be below 1.010, and there must be some period within the day when the urine is entirely free from albumin. There must be no casts present as a rule. If the patient is otherwise healthy and the urine perfectly normal, a few hyalin casts may be present, without necessarily requiring the rejection of the case.

**Diabetes.**—Whenever there is any sugar in the urine the case is always to be considered as extremely doubtful. Insurance companies recognize, however, that alimentary glycosuria may occur, and that this does not necessarily mean the approaching death of the patient. If there is glycosuria and no other sign of diabetes, that is, if the patient is not thirsty, does not pass large quantities of urine, has not the tired feeling nor the tendency to cramps characteristic of diabetes, the case may be taken under consideration. A certain number of these cases are now accepted as substandard risks. There are no hard and fast rules for them, however, and each case must be judged by its individual merits. As a rule, cases in which sugar appears in the urine, except at the high tide of digestion, are to be considered as risks not worth accepting at any rates.

Dr. Charles Schramm, opening the discussion, said that it is interesting to realize that insurance companies have taken up this question of the insurance of substandard lives, and especially of accepting risks on patients suffering from slight amounts of valvular heart disease. There seems every reason to think that the statistics gathered under these circumstances by the companies will prove of great assistance in enabling medical men to make a more exact prognosis in these cases than it has been possible to make hitherto. There is no doubt that the companies will find such risks not so forbidding as they have been considered, since comparatively long life is by no means incompatible, as any practitioner of large experience in the cases of heart disease is sure to know.

**Medical Experts in Life Insurance Trials.**—Dr. Reynolds Wilcox said that his experience in the medical aspect of life insurance has consisted in opportunities for giving expert testimony in order to compel the payment of death claims. Dr. Wilcox is of the opinion that the medical examiners for life insurance companies are prone to reject many risks that would undoubtedly prove opportunities for profitable insurance. On the other hand, by a curious opposite anomaly of judgment, many cases suffering from affections sure to bring a premature end to life have succeeded in passing medical

examiners. Dr. Wilcox has seen individuals suffering from diabetes, from arterial degeneration, from severe nephritis, from pulmonary tuberculosis, with a cavity already present, secure policies which matured by death within a year or two. This failure on the part of medical examiners to recognize grave diseases is due to the fact that their examination is made by rule of thumb, by routine method without regard to individual cases.

**Insurance Companies' Directions.**—Some of the directions given to life insurance examiners by their Boards of Medical Examiners for the companies are difficult to understand. For instance, there seems to be a special insistence on the danger of tuberculosis after typhoid fever, which somehow is not borne out by the clincial experience of medical men who devote themselves more especially to the treatment of these affections. On the other hand, the time limit as to tuberculosis and its dangers in life insurance seems to be set too early. As a rule, it is presumed that if patients have not suffered from tuberculosis before middle life, they will not develop it afterward. Dr. Wilcox collected the statistics of some eight to ten thousand disabled soldiers in various soldiers' homes in the United States and found that in very many cases the origin of tuberculosis occurred at an age far above middle life, often after fifty, sometimes after sixty, and at times when, by the rules of most insurance companies, the danger from the development of the disease would be considered to be passed.

**Cancer in Life Insurance.**—Dr. William B. Coley said that insurance companies are wise in taking every precaution with regard to ruling out cancer cases. With regard to the family history of cancer, his experience has shown him that in most cases it is extremely difficult for even the surgeon in attendance at a case to obtain this without concealments. In a recent case Dr. Coley was brought in close relations with an interesting case, in which the insidiousness of cancer was well illustrated. A young business man took out a policy for $50,000, passing the medical examination without any difficulty. At the time of the examination he had a sore thumb, but as this was due to an injury acquired while letting down the office curtain, it was not considered important. During the healing of the wound the condition resembling that known as a run-around developed, and healing became very slow. During the healing process another pathological condition developed, which ultimately proved to be melanotic sarcoma. Amputation was performed, but to no avail, and the man died two years later of general sarcomatosis. The company refused to pay the policy, because the beginning of the fatal conditions were present when the risk was assumed, and had they been informed of their character they would have refused to issue the policy. The courts decided, however, that the applicant was in good faith, and so the policies had to be paid.

**Examiners' Failures.**—Dr. Follen Cabot said that examiners for life insurance companies are appointed and set to work very frequently without sufficient instruction. They are warned as a rule not to let little things disturb their judgment, and soon learn that the office prefers that a risk be reported either as good or bad. This requires definite decisions, often when such decisions are not easy to make. Regular examiners are paid a small salary, and yet the companies expect gilt-edged work. This is a very short-sighted policy, and is undoubtedly responsible for many of the failures of the medical department properly to eliminate risks, as they come in, and also accounts, at times, for the refusal of risks which would have proved paying investments for the company. Dr. Foote said that the slight amount of increase in premiums for the increase in age does not seem quite just. The expectation of life would seem to decrease with greater rapidity than the advance in premium.

**Albuminuria and Glycosuria.**—Dr. Ogden said that life insurance companies put too much weight on the presence of albumin in the urine, and lay not quite enough stress on the presence of sugar. Of course, when casts are present there is no question but that the risk should be rejected. Under middle age, however, slight amounts of albumin are often present in individuals who live to a good old age. On the other hand, intermittent glycosuria under middle age must be ruled out. It is before middle life especially that the presence of sugar in the urine is of significance. As a rule, it will not be long before the glycosuria takes on the malignant type, which characterizes diabetes in the second and third decade of life.

**Life Insurance Examination as a Test of Prognosis.**—Dr. James J. Walsh said that a recent interesting case of uncertain prognosis, in which the family doctor, in order to test his own knowledge, suggested that his patient should apply for life insurance, had recently come under his observation. At the age of about fifty years a prominent merchant in a rural town developed some dyspnea on exertion. As he had been gaining in weight, he did not consider this of great significance, but applied to his family physician for a tonic. His family physician found some signs of mitral trouble. Under the use of digitalis the murmuring sound completely disappeared, and the physician was not sure whether there had been anything more than a functional murmur existent for a time owing to over-exertion. He said nothing to his patient, but suggested that if he were not carrying much life insurance that this would be the time to apply for it, especially as the result of the examination would probably do away with any anxiety he might have about his health. The merchant had been approached by an agent several times previously and had been hesitating as to the question of life insurance. The next time the agent called he applied for a policy for $50,000. He was carefully examined by three physicians, who passed him, and he secured his policy. He died two and a half years later, with evident signs of severe mitral disease.

In closing the discussion, Dr. Knight said that for the acceptance of every substandard risk there is a discussion of five high officers of the company who are selected for this purpose. While it is the policy of every insurance company to pay all honest death claims, the treasurer's office being open for this purpose every day in the year, even holidays, it is easy to understand that life insurance companies could not be made to pay if they did not endeavor to do away with every possible loophole for fraud. His own company employed no salaried men as medical examiners, and paid full fees for each medical examination, and thought that this was the best method to follow. The medical examination does not after all count for so much in eliminating undesirable risks. In the low amounts of insurance no urinary examination, for instance, is required, and yet the death-rate from albuminuria is not high. Very few men suffering from glycosuria are accepted as risks. Out of 10,000 to 12,000 substandard policies issued by his company, not more than nine or ten are sufferers from glycosuria. Occasionally, of course, in spite of apparently every precaution, mistakes are made and bad risks assumed. In a recent celebrated case the man was insured for over $400,000, distributed in a number of companies. Just after an embezzlement he died suddenly, and it was thought that he had died from poisoning, self-administered, and as there was a suicidal waiver clause for the first year's insurance this would make the policies void. At autopsy, however, he proved on excellent evidence to have died of acute nephritis.

## CHICAGO SURGICAL SOCIETY.

*Regular Meeting, held June 1, 1903.*

The President, John B. Murphy, M.D., in the Chair.

**The Treatment of the Complications Attendant upon Chronic Gall-stone Disease.**—Dr. John B. Deaver, of Philadelphia, read this paper (by invitation). In acute obstruction of the common duct, operation is not to be thought of until increasing jaundice or a period of chronicity, with fever and rapid pulse, indicate the need of such interference. Chronic gall-stone obstruction, either with its increasing jaundice or the intermittent form, has called for surgical intervention, because of the liability of such stones to cause strictures, ulceration, fistulæ or damage to the pancreas and to aid in the production of suppuration of the liver ducts, when infection becomes superadded. As infection of a varying degree is practically always associated with the formation of gall-stones, and as such infection is surely accompanied by a catarrhal condition of the mucous membrane of the common duct, the presence of a calculus, even if not sufficient in size to produce jaundice, will impair the drainage of the duct, and induce a train of symptoms causing chronic invalidism.

The preparation for a gall-stone operation differs in nowise from that for any other, except in the presence of jaundice, when calcium chloride may be administered for three or four days previous to operation, in doses of 20 to 30 grains, three times a day. The use of a sand pillow is a useful adjunct in order to arch the spinal column and give a better exposure to the gall-bladder region. The author usually has it placed somewhat below the liver level, which is the point recommended by Mayo Robson, and places the table in a slight Trendelenburg position, three or four inches.

As to the incision, he fails to see any advantage in that made by Kehr; it is not only unnecessarily long, but by dividing two-thirds of the rectus muscle must certainly predispose toward hernia. The incision originated by Mayo Robson gives a perfectly satisfactory exposure of the field of operation, and by splitting the rectus muscle instead of dividing it, will insure a much stronger abdominal wall. After opening the peritoneum and inspecting the field of operation, the intestines are best kept out of the way by a few, well placed gauze pads, and over these several flat marine sponges. He uses the latter because, in spite of all precautions, some bile occasionally "spills" and the sponges soak up the fluid better and more quickly than gauze. In disposing the gauze and sponges, particular care must be given to the subhepatic space, and the region above and below the gastrohepatic omentum. The retention of purulent products in any of these fossæ may give rise to serious consequences later. He hardly believes that Kehr's method of performing hepatopexy by stitching the liver to the posterior parietal peritoneum is necessary.

The preparation of the field of operation calls for the expenditure of some time and attention to detail. He would no more think of cutting adhesions or searching for a stone without having protected the general peritoneal cavity than he would rupture a periappendiceal abscess in the absence of adequate gauze protection to the intestines. Adhesions should then be dealt with, and while in some cases a few ligatures and the use of the finger and scissors would be sufficient, in others the most extensive and careful dissections will be called for. Every band of adhesion should be carefully tied and divided, and in the separation of those of a more voluminous nature bleeding should be guarded against by the closest scrutiny. After freeing the adhesions, the gall-bladder becomes exposed and the right free border of the gastrohepatic omentum is traced to the duodenum. The gall-bladder holds the same relation to the common duct that the anterior longitudinal band does to the appendix, and the exposure of the gall-bladder and the free border of the omentum is the exposure of the field of the common duct.

A nice question may arise, to be decided when a dilated and displaced stomach due to pericholecystic adhesions has caused marked gastro-intestinal symptoms. The great advances and the brilliant results of a gastro-enterostomy may well cause an operator to pause and consider whether he can successfully break up all constricting bands and prevent their recurrence, whereas a gastro-enterostomy in addition may cause complete relief of the symptoms. Personally, he believes one should be governed by the circumstances of each case; the risk of opening the stomach and intestine is not absolutely *nil*, and the necessity of avoiding peristalsis for some hours after operation would perhaps cause extensive readherence of all raw surfaces.

Fistulæ require great caution in their management, in order to avoid soiling the peritoneum with bowel contents by inadvertently opening the intestine when cutting a supposed adhesion. These cases call for the expert use of the needle and thread, and require the operator to be the master of all situations and emergencies.

From a report up to 1897, which Dr. Murphy furnished to Mayo Robson, cholecystduodenostomy had been performed with the aid of the anastomosis button in 67 non-malignant cases, with only 3 deaths, these being due to continuous hemorrhage from laceration of the liver substance on the seventh day, to cholemia on the fourth day, and to septicemia on the fourth day, respectively. Of his 12 malignant cases, 10 died, giving a mortality of 83.3 per cent. It is important, before performing this operation, to observe whether the cystic duct is unobstructed, because if the gall-bladder is small, on account of loss of function, the operation is useless. Should the cystic duct be partially or completely obliterated, hepatic drainage is indicated, and when the gall-bladder is diseased its excision should be performed in addition.

The question of drainage occupies a prominent place in the technic of all gall-bladder operations. There is never any doubt in the mind of the operator as to the wisdom of draining the suppurative forms of cholecystitis and cholangitis. With a gall-stone partially obstructing the common duct and a shrunken, thickened gall-bladder, the most rational operation at first would seem to consist in removing the stone, closing the duct, and excising the gall-bladder. In addition to the tubular drainage, in such cases, he places two strips of gauze, one leading to the stump of the gall-bladder, the other slightly spread beneath the wound in the common duct. It is safer to drain the hepatic duct at all times, not only on account of infection, but owing to the likelihood of overlooking stones in the hepatic ducts. Kehr even goes so far as to state that after choledochotomy with suture, "even the most skilled surgeon must count upon overlooking stones in from 10 to 15 per cent. of his cases." The speaker uses a smaller-sized tube than the latter author when draining.

The question, When is the time of election for performing a surgical operation upon patients suffering with cholelithiasis, has been answered time and again by surgeons. Mayo Robson believes that "as soon as gall-stones give serious trouble, their removal by operation is the most rational method of treatment, since it is only from the complications, which in many cases of cholelithiasis arise sooner or later, that any danger after operation may be apprehended." It is the opinion of Dr. Deaver, after a rich experience in complicated and uncomplicated cases, that operation should be re-

sorted to as soon as it is definitely known that gall-stones are present. The recent statistics published by Kehr speak eloquently for the results of early operation. In 535 uncomplicated laparotomies for gall-stones, the mortality was 3.5 per cent. In 71 simultaneous operations in inoperable carcinoma of the gall-bladder, common duct or liver, in diffused suppurative cholangitis, diffused suppurated peritonitis and sepsis, the mortality was 97 per cent., nearly every case, 69 out of 71, succumbed to the deadly spread of infection or to carcinoma possibly the result of chronic gall-stone irritation. In 114 operations on the stomach, intestines, pancreas, liver, kidney, etc., 24 per cent. died. These cases were those in which extensive adhesions, chronic pancreatitis, or various changes in the liver and kidney made the operation difficult and the anesthesia prolonged. Gall-stones, *per se*, never kill, and fatal infectious cholangitis is not common in the absence of a stone in the ducts. It is only in the presence of great adhesions, fistulæ, suppuration, pancreatitis, or disease of the liver and kidneys that the mortality rises in direct proportion to the grade of the complication. Operation is particularly indicated in those cases of chronic calculous cholecystitis, without jaundice, and with or without enlargement of the gall-bladder. Like the interval operation in appendicitis, with a chronic low-grade inflammation, perhaps a fecal concretion, and with more or less adhesions, the removal of the diseased gall-bladder can be performed with as much celerity and safety as can the amputation of such an appendix. Unoperated, they give rise to a train of symptoms, driving the unfortunate patient to the stomach specialist, or to places like Carlsbad. The stones are too large to pass the cystic duct, and the low-grade inflammation is responsible for a sequel of symptoms which lead to chronic invalidism.

Dr. William J. Mayo, of Rochester, Minn., said there are two important questions in connection with surgery of the gall-bladder and biliary passages, which are as yet unsettled: (1) In what cases shall we remove the gall-bladder? (2) in what cases is it wise to drain the bile to the surface? The majority of the complications of gall-stone disease are the result of delay, and that preceding this time there are diagnostic symptoms which would have enabled an operation to have been performed with much less danger. Should we, in the early uncomplicated cases of gall-stone disease, take the gall-bladder out, or is it sufficient to drain it for a time, until the biliary discharge is sterile? Without going extensively into the physiology of the gall-bladder, there is no doubt but that Murphy is right in believing that one of its functions is to act as a tension bulb, keeping the flow of bile steady instead of intermittent. This is unimportant of itself, but when the gall-bladder is suddenly cut off by a stone impacted in the cystic duct, there are not only symptoms arising from the retention in the cystic cavity, but there is usually some irritation of the liver from the increased tension and mild infection, shown in many cases by transient slight jaundice, etc. The liver soon accommodates itself to this change, and when the acute symptoms of obstruction are over such a gall-bladder can be tied off without liver drainage, but if the cystic duct is not obstructed and the gall-bladder still persists in the biliary circulation, in spite of the stones, the sudden tying-off of the cystic duct, without provision for the escape of bile, is liable to increase liver tension and coincidentally the infection of the liver ducts, and adds this condition to the usual risks of operation. It is altogether probable that in the majority of cases this would do harm, yet in the exceptional ones cessation of liver function and death may follow. As stones do not re-form after complete removal and drainage, it would seem to the speaker that the excision of the otherwise healthy gall-bladder, on account of gall-stones, subjects the patient to some unnecessary risks, unless some provision is made for hepatic drainage. The thick, contracted gall-bladder, with obstruction at the cystic duct, has lost its function and such a gall-bladder is the one in which we are liable to have future trouble from mucous fistula, adhesions, cancer, etc. Fortunately, by reason of the obstruction, the liver has become accustomed to the change in the extension, and such a gall-bladder can be removed without biliary drainage. He has never seen harm follow the ligation of the cystic duct in such cases, and this exists in about one-third of the cases as they come to the operating table. Stones in the common duct are the cause of cholangitis, and drainage of bile to the surface is necessary either by a cholecystotomy, if the cystic duct is sufficiently patulous for the purpose, or by leaving the incision in the common duct open, the latter being the safer method. To what extent is it necessary to provide bile drainage in cases in which there are no stones in the common duct? Cholecystostomy drains the hepatic ducts by the escape of bile to the surface, and all of experience have seen a patient doing badly, suddenly relieved by a discharge of bile in a previously dry wound. So true is this that often with a patient not doing well the drains are loosened, hoping to establish bile drainage, and, if one succeeds, recovery usually follows.

He has tried to classify his cases with regard to the necessity of hepatic drainage. The following is about the position he has temporarily assumed as a result of this study: (1) If the gall-bladder contains bile and the organ is distensible, if the gall-bladder be removed, bile drainage is provided for by cutting the cystic duct across and leaving it open. If such a patient is very obese, or has degenerative lesions of other organs, he prefers cholecystostomy. (2) If there are symptoms of a cholangitis, even of mild grade, he provides for bile drainage, and if the condition is acute, the drainage must be free. (3) If the gall-bladder contains cystic fluid, but no bile, and the patient has symptoms of cholangitis, he removes the organ and cuts the cystic duct below the obstruction, to permit of bile discharge. If necessary, the cystic duct is split down to the common duct. (4) In a few cases he has directly opened the common duct for the purpose of securing liver drainage, but it is very rare that this is necessary, unless there are or have been stones in the common duct and it is dilated. The cystic duct ordinarily can be advantageously used for the purpose, although in a few instances he has found it necessary to cut it off flush with the common duct, leaving a lateral defect in its wall for drainage purposes.

This brings up the question as to how much danger of peritonitis there is as a result of bile leakage into the peritoneal cavity. If there is free gauze drainage with or without tubage, there is but little danger of peritoneal infection from the bile. He has never seen a case of death from this cause; but the drainage should be attached to the proper point by a catgut suture to prevent its floating away by the bile discharge or displacement by the action of the diaphragm upon the liver. If the common duct is greatly dilated and after removal of the calculi there is considerable detritus, the end of a rubber drainage tube is inserted just into the duct opening and secured by a catgut suture. If this condition does not exist, tubage of the common duct is unnecessary.

To sum up: Cholecystectomy is to be preferred if the patient is otherwise in good condition. If the cystic duct is obstructed and the gall-bladder contains only cystic fluid, ligation at the cystic duct, without provision for hepatic drainage, is safe. If there be any infection of the hepatic ducts, bile drainage is essential.

**Gall-stones and Gall-bladder Diseases from the**

**Standpoint of the Physician.**—Dr. Norman Bridge contributed a paper on this subject. He stated that the physician can often present the urgency of an operation to the patient better than the surgeon. Most people dread operations, and many suspect the surgeons of having undue enjoyment in the act of operating and of being biased by visions of large fees. The physician is, for these reasons, a more acceptable counselor, but even he, in these later days, says the essayist, is not free from the suspicion of seeking a part of the surgeon's reward. The author cited cases which vividly illustrate the long continuance of gall-bladder symptoms without recognition. Whether operation shall be done in all cases of proven gall-stones, or of suppuration or distention of the gall-bladder, is the same question over again of the misfortunes of the appendix. Cases become quiescent, or recover and remain so for years, even with gall-stones, the patients dying of other diseases or of old age. Hence one camp of doctors contends that in all such cases we should wait; not operate until forced to it by some urgent symptoms or situations. The other camp says that, for the sake of safety, operation should always be done promptly, since the next attack might be fatal. Both are in part right; neither can prove the other wholly wrong.

People are taking great personal risks in manifold ways all their lifes, and with the lightest thought. But if one suffering from cholelithiasis, to the extent of producing marked symptoms, would minimize to the lowest point his danger of death from it, he will probably have it dealt with surgically, always provided he has a surgeon who is wise in pathology and procedure, as well as expert in technic, and provided the patient has good vital organs. That statement is still true of the diseased appendix; it is true of gall-stones and gall-bladder infection as well. All cases of chronic cholelithiasis, where the suffering has led to the opium habit, should be operated. Every case of known distention of the gall-bladder by fluid of any sort is in constant peril, and should be operated, if possible. If there is reason to believe the bladder contains pus, operation is urgently demanded. And in all cases where frequent recurrences, or the persistence of symptoms indicate the progressive contraction and fibrosis of the gall-bladder, operation should be insisted on, for in these there is constant danger of an explosion of infection that may destroy life.

All cases of proven gall-stones or gall-bladder trouble are proper subjects for surgical consultation, whether they are to be regarded as surgical cases or ever come to operation. Whether operation is to be done or not, when conditions do not sound the insistent need of an operation, or the patient declines, or the physician sees reasons against an operation, proper medical treatment should be instituted always, and persistently carried out. This is as true of the gall-stone troubles as it is of those of the appendix.

What are such measures? In the acute cases, there should be absolute rest of the body. Rest of the stomach and bowels to the extent of starvation for some days is best, especially where peritonitis is present or threatened. Nutrient enemas may be allowed tentatively, but never nutrition by the stomach in such cases. The upper abdominal organs must be kept still, not be shaken about by persistaltic movements.

In the subacute and chronic cases the daily full flushing of the bowels by alkaline laxative waters is useful, but it is irrational to suppose that gall-stones are thus washed away. Nor do olive oil or any other of the pretended expulsive agents have the smallest effect. The thing that happens is probably merely the elimination of effete matter, thus increasing the physiologic resisting power. This process is aided by a restricted diet of the most assimilable foods, and by general good hygiene.

Dr. Frank Billings, speaking from the standpoint of the internist, said that given a reasonable certainty of the presence of gall-stones in the gall-bladder or ducts, it calls for their removal by means of the surgeon's knife, with the statement modified to this effect, namely, that where there exists some disease of other organs of the body, as the kidneys, or the heart, which would render the use of an anesthetic immediately dangerous to the health of the individual, it was questionable whether operation should be done. If gall-stones are acute in their manifestation, his advice is to wait until their symptoms have diminished or subsided. If attended with jaundice, to wait a reasonable time to see if it does not diminish, and if it does to attempt to improve the coagulability of the blood by the use of calcium chloride. In recent years, by means of calcium chloride, the coagulability of the blood has been increased or improved to such an extent as to make surgical operations less dangerous than before it was given. He would go further than Kehr, if he understood him correctly, and say that if there are symptoms of gall-stones in the common duct, and they subside, and if following that, within a reasonable length of time, there are further symptoms or indications of gall-stones, he would urge operation. He understood from the paper read by Kehr at Washington that he (Kehr) would not operate on such cases. While the speaker made this statement from a medical point of view, of operating on gall-stone cases when the evidence was clear that they were present, surgeons should not forget that they owe a great deal of what they know to-day to Pasteur and Koch. It is the work of Pasteur, Koch, Lister and others that has enabled surgeons to open the abdomen in these cases, and to treat them successfully. Dr. Billings then recounted briefly the symptoms of cholelithiasis and pointed out their peculiarities. He said the medical treatment of gall-stones was instituted long before surgeons opened the abdomen for the relief of this condition. The Carlsbad treatment has been in vogue for years, and surgeons should not censure medical men too much for sending their patients to Carlsbad or resorting to medical treatment, when it was known that a celebrated surgeon who, two years after operating on his own father for gall-stones, was attacked himself, but instead of undergoing an operation he went to Carlsbad for treatment.

Dr. Arthur Dean Bevan said that in a discussion as broad as the one on the subject of cholelithiasis, he took it that brief conclusions arrived at from a review of one's own experience would be in order, and with such an idea in view he submitted the following: (1) Gall-stone disease is due to a mycotic invasion of the bile tracts, and is exceedingly common. From my dissecting room experience, it occurs in 16 per cent. of such cadavers. (2) In the vast majority of cases of gall-stone disease, the patient does not suffer from the existence of the condition. (3) A close parallel cannot be drawn between cholelithiasis and appendicitis, and the conclusions which we have all arrived at in appendicitis, *i. e.*, that a diseased appendix should in practically all cases be operated on, cannot with equal force be applied to cholelithiasis: (*a*) Because the disease, in its first manifestations, does not carry with it nearly the amount of danger to the patient as does appendicitis; (*b*) because of the enormous number of individuals who have gall-stones many have slight, single or very infrequent manifestations of the disease, which are speedily recovered from, carry little danger, and a good prospect of permanent recovery. Several of his colleagues have had single attacks, and have been advised by both surgeons and internists to await developments and postpone operative interference until the indications warranted it. (4) As a corollary to the above, the hygienic

treatment, *i. e.*, exercise, diet, salines, is indicated in cholelithiasis, as a rule, in the first manifestations of the disease. (5) Surgical treatment is indicated when the manifestations of the disease are repeated, and especially when they are frequent and severe. Surgical treatment is demanded when we have (*a*) an infected gall-bladder; (*b*) with stone or obstruction of the cystic duct; (*c*) with stone or obstruction of common duct. (6) With stones still confined to the gall-bladder, cholecystotomy with drainage is the operation of choice. (7) With stone in the cystic duct, or obstruction of cystic duct, cholecystectomy is the operation of choice. (8) With stone in the common duct, choledochotomy with drainage is the operation of choice. (9) With stone in both cystic and common ducts, cholecystectomy and removal of stone from common duct, and drainage of common duct, is the operation of choice. (10) With obstruction of common duct from chronic interstitial pancreatitis or carcinoma, drainage of the bile tracts through the gall-bladder is the operation of choice. (11) In the cases of cholecystitis and cholangitis simulating gall-stones, drainage of the gall-bladder should be carried out, and with this probably the use of salicylate of sodium, which is excreted through the bile, and has seemed to exert a definite local antiseptic effect. (12) To expose the bile tracts, the incision which he introduced in 1898, as modified by Weir and Mayo Robson, gives the best access to the region, makes the operation in difficult cases much easier, saves valuable time, and is least likely to be followed by hernia. (13) The mortality from gall-stone operations is surprisingly small in uncomplicated cases. He had no deaths in more than one hundred cholecystotomies, and in more than 20 cholecystectomies had but one death in 14 cases of obstruction of the common duct. (14) The prospects of permanent cure after operative removal of gall-stones are very good. The recurrences of symptoms are almost always due to incomplete operations, *i.e.*, leaving some stones or the doing of a cholecystotomy where a cholecystectomy should have been done. (15) Personally, he had seen little evidence pointing to gall-stones as a factor in the production of carcinoma, and therefore inclines the belief that carcinoma favors gall-stone formation, and is the cause and not the effect where these two conditions co-exist. (16) The modern surgical treatment of cholelithiasis is, with the exception of the surgical treatment of appendicitis, the most valuable addition that has been made to medicine during the last twenty years. Inasmuch as the general practitioner sees most of these cases, in their early history, it rests with him whether or not this valuable knowledge will be made the most of and accomplish the greatest amount of good.

Dr. Deaver, in closing the discussion, said that the points brought out by Dr. Mayo relative to the non-removal of the gall-bladder in certain cases were very apropos. In the past he had made the mistake of tying off the cystic duct and removing the gall-bladder when he should have done a cholecystotomy. However, nature had come to the rescue, had forced the ligature off, established a biliary fistula, and had saved the patient's life.

The remarks of Dr. Bevan were in harmony with the position taken by most surgeons with regard to the treatment of cases of cholelithiasis.

A short time ago, in an address delivered in this city, the speaker said the surgeons of the East had to bow to the surgeons of the West, and after hearing the remarks of Dr. Billings, he was prompted to say that the medical men of the East would now have to bow to the medical men of the West. If the medical men of the East took the advanced position enunciated by Dr. Billings in regard to operative intervention in cases of gall-stones, it would not cause surgeons to have so many gray hairs, to spend so many restless nights, and to make them prematurely old.

---

## SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

*Meeting of June 3, 1903.*

The President, Robert T. Morris, M.D., in the Chair.

**Reportable Diseases.**—Dr. Hermann M. Biggs read a paper with this title with the object of eliciting some discussion as to the type of diseases which should be considered reportable. Within the last two years, he said, the Health Board had considerably increased the list of reportable diseases. At the present time this list comprised typhus fever, yellow fever, typhoid fever, scarlet fever, plague, cholera, measles, diphtheria, smallpox, chickenpox, whooping-cough, tuberculosis, malarial fever and contagious ophthalmia. In the case of malarial fever notification was required only from institutions, though private physicians were requested to notify such cases also. The speaker thought the time had arrived when a material change should be made in the attitude of the health authorities regarding reportable diseases, and that the list should be considerably increased and grouped somewhat differently. In his opinion, all the more important diseases which were infectious should be included in the class of notifiable diseases. Under the term, infectious, he would include all those caused by the simplest forms of life, and would rearrange their classification. The following tentative classification was then presented:

I. **Compulsory Notification.**—(*a*) Contagious diseases, *i.e.*, those which are very readily communicable, viz., measles, rubella, scarlet fever, smallpox, typhus fever and relapsing fever; (*b*) Communicable diseases, *i.e.*, diphtheria, typhoid fever, Asiatic cholera, tuberculosis of all organs, plague, tetanus, anthrax, glanders, epidemic cerebrospinal meningitis, leprosies, infectious diseases of the eye, puerperal septicemia, erysipelas and whooping-cough; (*c*) The indirectly communicable diseases, *i.e.*, communicable only through an intermediary host, viz., yellow fever and malaria.

In order to secure important information it was considered advisable to have reports on the following groups, notification to be compulsory only in the case of institutions:

II. **Non-Compulsory Notification.**—(*a*) Communicable diseases: Influenza, lobar pneumonia, bronchopneumonia, infectious diseases of the gastro-intestinal canal; (*b*) Parasitic diseases of the skin: Scabies, tinea tonsurans, impetigo and favus.

It was not intended that the Health Department should have surveillance over these diseases, but it was necessary to have information regarding them in order that they might be limited and controlled. For example, by such measures much valuable information could be obtained concerning malaria. It was well known that in large cities, particularly, there were many unnecessary cases of puerperal septicemia, and the notification of this disease would enable the health authorities to determine the causes, and would serve as a salutary restraint upon the abortionists. Pneumonia stood first as a cause of death in New York city, and yet the sanitary authorities had no adequate information as to the extent of this disease or as to its epidemiology. A new field of investigation had been recently opened in connection with the infectious character of summer diarrheas, and it seemed probable that some forms were much more easily preventable than would have been supposed from our previous knowledge. Investigation had shown that serious outbreaks of diarrhea and dysentery

had occurred in certain institutions and in certain areas which were in all probability preventable, and yet the sanitary authorities had no accurate and definite information regarding them. A serious objection that might be urged against the proposed plan was the largely increased labor that would be incurred by physicians. There were 35 diseases included in the list given. The English authorities paid a fee for each disease notified, and it might be possible to adopt that plan here, but this had not been the custom, and there were no funds at the disposal of the sanitary authorities for this purpose. The Health Department of New York city had endeavored to make some return to physicians for their labor in notification by aiding them in diagnosis by bacteriological examinations of certain classes of cases. This system must be admitted to have a certain monetary value, for, it should be remembered that the great mass of physicians were not prepared to make such examinations themselves, and the usual fee charged at the laboratories for such an examination was five dollars.

**Ophthalmia Neonatorum.**—Dr. J. H. Woodward said that there was no doubt in the minds of ophthalmologists that ophthalmia neonatorum should be a reportable disease, but whether the ophthalmias generally found in our schools should be included in this class was one open to much discussion, and without further thought he would not be willing to say that they should be notified.

Dr. W. J. Chandler said he desired to second all that Dr. Biggs had said, for he had felt for a long time that not only should these diseases be reported, but that *all* diseases should be reported to the sanitary authorities, for the accumulation of statistics and the obtaining of proper deductions therefrom. Some years ago the United States Government endeavored to collect such statistics from the local inspectors, but it was not pushed to any extent.

Dr. H. J. Boldt said he had been impressed with the paper so far as it treated of all septic infections of the puerperium. There had been such a law in Germany for a number of years, and he thought physicians as a class would look upon this proposition as very desirable. This would be especially so if the sanitary authorities took pains to see that midwives responsible for such infections were debarred from practising until the danger of spreading infection had passed. He recalled some years ago a small epidemic, with a number of fatalities, arising in the practice of one midwife. He hoped the proposed action would be taken at a very early date.

Dr. A. Brothers said that the Society was not only indebted to Dr. Biggs for this paper, but for much of the work of the Board of Health for many years past. The speaker said that years ago before taking up special work he had practised among the slums, and he knew very well what a great change had been wrought in these localities. The privilege of having exudates examined free of charge, the privilege of having material sent for inoculation, and even of having injections made by the Board of Health physicians all represented a great money value. With regard to the notification of many diseases, he would say that from the standpoint of the general practitioner it often happened that the physician was suspicious of the nature of a disease, and yet did not care to have the patient or his friends know more definitely about it at the time. This occurred more particularly in the early stages, especially in cases of tuberculosis. Most fair-minded physicians had overlooked this, but there were many physicians who felt that such regulations exposed them to much unfavorable and perhaps unfair criticism. From the standpoint of the obstetrician he could speak feelingly because he had been brought largely in contact with midwives, and from his recollection of this experience he foresaw much trouble arising in this connection; nevertheless Dr. Boldt was right in saying that the sanitary authorities should have information on such matters. The suspension of midwives from their work would not be sufficient to meet the difficulty; he had long claimed that the people who gave the midwives their privilege to work were the ones who were to blame. In this country there was no real system of education for midwives as was the case on the Continent. Some of the so-called midwives had had no training, but had borne several children themselves and had seen two or three other confinements. He had observed more mischief perhaps from the imported midwives because they "knew it all." Then there was the home product, a class of women who, after a very short course of instruction, received a diploma from a school, the instructors in which were physicians of no standing in the community. If the paper of this evening could bring about some remedy for this evil alone a very great advance in the control of puerperal infection would be made.

Dr. Floyd M. Crandall said that there could hardly be any doubt as to the importance of the reporting of infectious diseases and perhaps of all diseases for the purpose of tabulation and study. The great obstacle would be found in the objections of the general practitioner. One trouble was carelessness and forgetfulness in the matter of notification. Again, in many families a considerable pressure was brought to bear upon the physician to prevent the proper notification. A considerable time for education and training would be necessary before such a system could be made to work smoothly, and hence, the sooner the proposed plan was inaugurated, the better. He thought too much could not be said by the profession of this city with regard to the value of the work done in the health department by Dr. Biggs.

Dr. Louis A. di Zerega asked Dr. Biggs if he thought it was possible to report every case of typhoid within twenty-four hours after first seeing the case. He would also like to know the attitude of the Board of Health with regard to gonorrhea, syphilis and leprosy.

Dr. Gouley thought that all of the cases to which Dr. di Zerega had made reference could be reported by simply omitting the names, which were of comparatively little importance to the sanitary authorities.

Dr. Biggs, in closing the discussion, said he desired to bring about a different attitude on the part of the profession and people toward the health department and its work. The feeling was, and had been, that as long as any disease was reported to the health department, this notification became public property, and the health department assumed sanitary surveillance. The health department did not assume such surveillance except in the case of those diseases which were generally regarded as contagious or very readily communicable, such as measles, scarlet fever, smallpox, chickenpox and typhus fever. The reporting of chickenpox was required not because that disease in itself was an important one, but because a large percentage of the localized outbreaks of smallpox had, in the experience of the health department, come from unrecognized and very mild cases of smallpox which had been regarded as chickenpox. For that reason the department required that every case of chickenpox occurring in the adult be seen by a diagnostician of the department. Although last year about 15,000 cases of pulmonary tuberculosis were reported to the health department, it was found still that many practitioners had a strong feeling against the reporting of such cases. However,

the same men who would decline to report a case of tuberculosis as such would send a specimen of the expectoration for examination by the department. This attitude evidently indicated the fear that the health department would make such notification public property, and would assume sanitary surveillance. The department had never done this except in tenement and lodging houses, and did not even then make inspections or take any action, if the physician reporting it was a private physician, and did not desire the health department to take any such action. With regard to pneumonia, influenza and the diarrheal diseases, he would say that the object of notification was not that the health department desired in any way to embarass the physician but rather to assist in determining what unsanitary conditions had existed, and had been potent in the production of these diseases. He knew very well that from time to time there was ground for the feeling of antagonism between the private physicians and the health department, but it was impossible with a corps of three or four hundred inspectors furnished to the department by the civil service board to have everything working satisfactorily. These persons could not be removed from office by the department except for very good and definite cause. If improper conduct on the part of the inspectors were promptly reported to the sanitary authorities the matter could be easily corrected, but instead of this it was the rule for the profession generally to nurse their wrongs rather than forward the particulars of their complaint to the proper authorities. Within a little over a year 35 inspectors had been dropped because of their making false returns of their work. The same thing was true to a large extent with regard to the foreign element of the tenement house population. He had the feeling that if the list of diseases presented by him were very much increased the attitude of the people toward the health department might be changed because of a better knowledge of the true functions of that department. To the old list of diseases in which notification was compulsory had been added only glanders, epidemic cerebrospinal meningitis, puerperal septicemia and erysipelas. At the present time more than 80 per cent. of all the cases of pulmonary tuberculosis occurring in the Borough of Manhattan were reported. The notification of venereal diseases had received very careful consideration. He saw no objection to the reporting of such diseases without names, yet a pretty large experience had taught him that there was little to be gained. Physicians were too busy to attend to such work unless there was some spur, such as would arise from tracing these reports. Again, he had been a little at a loss to know what the sanitary authorities would do even if these cases were reported, and some person who had contracted a disease of this kind should come to the health department and ask why he had not been protected from this known source of infection. The question had been asked with regard to the notification of typhoid fever; he would answer that the law specified that notification should be made twenty-four hours after the *recognition* of the disease, for, of course, it could not be reported before it had been recognized. The reporting of cases did not involve any notoriety, for the records of the department were not open to the public except so far as concerned the contagious or very readily communicable class of diseases. Cases of leprosy had been reported to the department, and they had been at a loss to know what action to take. It was not desired to keep such persons on North Brother Island for the rest of their lives, as there were no recorded cases in which this disease had been spread here by contagion. Numerous attempts had been made to secure legislation for the regulation of midwives; at the present time nothing was required to become a midwife further than a statement, signed by two physicians, that she was competent. He believed if puerperal septicemia were made a reportable disease, and the responsibility for the large number of such cases be fixed upon the midwives, it would be possible to obtain legislation for their control.

Probably no one had any conception of the prevalence of trachoma in the public schools before the crusade made last year by the health department. Since the first of the present year a "tracboma dispensary" had been established with a staff of 17 physicians. Two of these operated in the morning, and two in the afternoon, and an average of 25 operations for trachoma, under anesthesia, were done daily. In addition to this work, between three and four thousand other eye cases had been treated each week.

With regard to the work on diphtheria in the tenements, the speaker said that about 50 new cases of diphtheria a week were treated in the tenements by the Board of Health physicians. These cases were usually neglected and severe ones, yet the mortality among these cases in the past year had been a little over 7 per cent. This gave some idea of what antitoxin had done in the control of diphtheria.

## AMERICAN PROCTOLOGIC SOCIETY.

*Fifth Annual Meeting, held in St. Charles Hotel, New Orleans, May 5 and 6, 1903.*

The President, Samuel T. Earle, M. D., in the Chair.

**"The Qualifications for Membership in the American Proctologic Society."**—The President delivered a very able address on this subject. Among other things, he said:

"Now is the time that our foundation is being laid, and the life and success of the Association depend upon the wisdom and discretion with which it is laid. We should look well to how our ship of state is trimmed and manned for each year's voyage, and have our course well mapped out to avoid the possible rocks and quicksands. And just at this time and juncture it seems to me that our attention should be called to a matter of the gravest importance to the continued life and usefulness of our Association, if it is to be the oracle of thought, purpose and action in all that pertains to proctologic work. The profession, and especially general surgery, is looking askant upon us, and is already prophesying that no great good can be accomplished in such a restricted field, and where work to be done is so near the surface, and within reach of the simplest observer. It is certainly expected that if we are to be recognized as leaders in this line of work, we must use as our foundation the cardinal principles that underlie both general surgery and medicine; in other words, we must be well grounded in the principles of both. In the organization of any association, it is almost impossible to draw the lines very tight; but when fairly upon its feet, there is nothing more important to its perpetuity and usefulness than the character and ability of the members it gathers in, and upon whom the position to be taken by the association depends. We cannot scan too closely, or from too many standpoints, those whom we delegate to carry on this work, and on whom its future success depends. It is quality, not numbers, that we most need; neither the one whose usefulness in proctologic work is interfered with by his interest in other departments of medicine or surgery, nor the pseudo-proctologist, should apply for member-

ship in this Association. The principal object the members of this Association have had, in keeping it a separate and distinct organization from the American Medical Association, has been that we might control the character of its membership, not from any selfish or narrow motives, as is evidenced by the welcome we have always accorded to those who are not members, to attend our general meetings, but for the broad and worthy object of enrolling upon our list of members only men of ability, learning, and with the avowed purpose of bending all their energies to advancing their knowledge of rectal medicine and surgery; because it is only by such means and men that we can hope to maintain our position as leaders and directors in this special line of work. Candidates for admission to the American Proctologic Association should be specialists in that line of work, meaning thereby that they devote their energies chiefly to it. I do not mean to say that we may not often get valuable suggestions from those in other lines of work, just as general medicine and surgery do from kindred sciences. If men in the various specialties of medicine would only be sufficiently honest and unselfish as to confine themselves strictly to their special work, there would be no necessity for the suggestions I am now making. We would have no such applicants. Show me a gynecologist or general surgeon who would hesitate for one moment to take a case of rectal surgery. I do not mean to say that our work is so complicated that others than rectal surgeons cannot perform such operations. A general surgeon can perform iridectomy, but who would be so foolhardy as to go to a general surgeon for such an operation when a competent oculist is at hand? So it is in ours, and in all other specialties: the man who confines himself to one line of work must be far below mediocrity if he cannot perform the operations in his line better than the general surgeon, or those in other special lines of work. In order to be recognized by this organization, one should be something more than a mere itinerant vendor of a pile ointment, or a pile doctor whose only armamentarium consists of a hypodermic syringe and a bottle of carbolic acid. We need well-educated, well-trained, and well-equipped men to carry on this work. We have submitted to us operations that require the most perfect surgical technic and the greatest skill, the coolest head and deftest hand."

**X-Ray Therapy in Ano-Rectal Diseases.**—Dr. J. Rawson Pennington presented this paper. The author dwelt upon the importance and efficiency of this agent in the treatment of pruritus ani, where the cause is local. The Society asked Dr. Pennington to continue his searches in X-ray therapy in rectal diseases.

**Tuberculous Ulceration of the Rectum and Anus.**—Dr. L. H. Adler, of Philadelphia, presented a paper upon this subject, in which he stated that tuberculosis is now recognized as the cause of a number of conditions occurring about the anus and within the rectum, the pathology of which was formerly obscure. The disease may be a primary process, but in the majority of instances it is secondary to similar changes in other organs. It may involve any portion of the rectum, or the skin about the same; its most frequent site, in the author's experience, however, is at the muco-cutaneous junction. The affection is always due to the tubercle bacillus. Any plan of treatment, to be of benefit, must, in a large measure, be directed to the general constitutional condition; and for this purpose, pure air, forced feeding, and all the hygienic and medicinal measures should be adopted as are employed in general tuberculosis. The local treatment has for its main objects the destruction of the tubercle bacilli, and the establishment of a healthy reparative process. The Paquelin or the galvanocautery, chemical caustics—such as chloride of zinc, nitric acid and acid nitrate of mercury—the curette, and the X-ray, have been employed for these purposes, and with varying results.

**Primary Tuberculosis of the Rectum with Report of Cases.**—Dr. Leon Straus, of St. Louis, presented this very interesting paper.

**Atony of the Rectum and Anal Sphincters; its Etiology, Pathology, Diagnosis and Treatment,** was the title of a paper presented by Dr. William Bodenhamer, of New York, in which he said: "Atony of the rectum and colon is most commonly met with in delicate women of a lax muscular fiber, and in those whose sedentary occupations lead to a neglect of the necessary measures to insure the regularity of the functions of the organ. It is also frequently met with in delicate children. In the treatment of rectal atony, the first consideration is to enjoin a strict observance of regular habits respecting a daily evacuation of the rectum, and this may be aided and often attained by simple means, such as the injection of half a pint of cold water into the rectum at the regular time of going to stool; cold being tonic, stimulant, and astringent, and acts somewhat similarly to nux vomica, by exciting the sensibility and contractility of the organ; but it should be discontinued as soon as the object of its use has been attained. In the more obstinate cases, however, the chief remedies should be nux vomica, alone or combined with some other ingredients, together with the employment of rectal injections composed of powerful astringents and tonic substances, with the intention of inducing contraction, corrugation, and condensation of the relaxed and weak muscular fibers of the rectum, by which they become shorter and firmer, and thus aid in diminishing the morbid organ to its normal dimensions and tone."

**Obstipation, its Causes, Effects, Diagnosis and Treatment.**—This interesting paper was read by Dr. John L. Jelks, of Memphis, Tenn. He stated that obstipation is the term used by proctologists to denote mechanical obstruction of the bowel, and is preferred to the generic term of which obstipation is one variety. He classed the causative factors as follows: (1) Extravisceral, (2) perivisceral, (3) visceral, (4) intravisceral. One of the chief facts which the author wished to forcibly express is that other factors may and do cause obstipation or obstructive constipation, and a careful discrimination should be made before an operation is performed upon a supposed obstructing rectal valve.

**Cautero-angiotribe.**—Dr. B. Merrill Ricketts, of Cincinnati, called the attention of the Society to this instrument as an efficient agent in the treatment of hemorrhoids and first degree rectal prolapse. This subject, together with that of "Hemorrhoids," by Dr. George T. Cooke, of Indianapolis, elicited considerable discussion, and Dr. Ricketts was instructed to make further report on the use of the angiotribe in the treatment of hemorrhoids. The discussion disclosed the approval of various methods of treatment of hemorrhoids, but none of them ideal.

**The Treatment of Anal and Rectal Diseases without General Anesthesia,** was the title of a paper by Dr. William L. Dickinson, of Saginaw, Mich., in which he said: "The treatment of anal and rectal diseases has been so long associated with that of general anesthesia that when a patient presents himself, and we have made an examination, we unconsciously begin to solve the mental problem of how he will take the anesthetic, and the number of days he will be confined to the house after the operation. The time-honored treatment of anal fissure by dilation, under chloroform, was both effective and speedy; but we can accomplish the same results, in a little longer time, by the use of cocaine or eucaine. Superficial fistula, ischiorectal abscess, ex-

ternal hemorrhoids, and many cases of internal hemorrhoids, can be operated upon under filtration just as well as general anesthesia. We owe it to our patients, and also to ourselves, to keep patients from going to the irregular practitioner, for as regular, educated physicians, we ought to be able to cope with all diseases of the rectum, in an intelligent manner, and thus give entire satisfaction to our patients. Our students should be taught that the greater number of our patients seek our advice and aid for ailments that respond readily to office treatment that can be given without general anesthesia.

**Molluscum Fibrosum of the Rectum in a Patient, the Subject of the Typical Skin Lesion—A Unique Case.**—This paper was reported by Dr. A. Bennett Cooke, of Nashville. This was probably the most interesting paper of the meeting. He stated that the feature of the case which justifies the adjective "Unique" is not the skin disease nor the occurrence of the multiple fibroid tumor in the rectum, but rather the association of the two conditions in the same individual and the further fact that the mucous and cutaneous tumors are identical in structure. He described the patient as emaciated, sallow, nervous and despondent; at least a dozen calls to the stool in twenty-four hours; sphincters relaxed and peri-anal integument excoriated from the irritating discharges; anal canal patulous, in spite of numerous successive abrasions. The proctoscope revealed the rectum almost completely filled with polypoid tumors, many of them ulcerated and bathed in a mucopurulent, blood-stained secretion of exceedingly offensive odor. The growths began in the lowest rectal chamber, varying in size from a bird shot to an almond; the largest were uniformly pedunculated, those intermediate in size had sessile attachments, and the smallest appeared as mere elevations under the mucous membrane, well embedded. It was found that the lesions extended well into the sigmoid colon, smaller in size, and were attended by less inflammation of the mucosa. Beginning below, the tumors were removed by tortion with the forceps, and by biting them off with a curette against the sharp end of the proctoscope. The hemorrhoid was rather free, so that it was possible to remove only a small number at a sitting. The operation was repeated from time to time during a period of three weeks, when the bowel, as high as could be seen, was clear of all but the smallest tumors. Sixty of the growths were removed; no anesthetic was employed. Dr. Cooke appended a report from a pathologist, which demonstrated the identity of the skin and rectal lesions. The production was considered a valuable contribution to proctologic literature.

The Society elected the following officers for the ensuing year: President, Dr. William M. Beach, of Pittsburg; Vice-President, Dr. Leon Strauss, of St. Louis; Secretary-Treasurer, Dr. A. Bennett Cooke, of Nashville. Executive Council: Dr. Samuel T. Earle, of Baltimore (retiring President), Chairman; Dr. George B. Evans, Dayton, O., and Dr. John L. Jelks, Memphis, Tenn.

The Society adjourned to meet in Atlantic City, in June, 1904, on the first and second days of the meeting of the American Medical Association.

## BOOK REVIEWS.

Tuberculosis. By Norman Bridge, A.M., M.D., Emeritus Professor of Medicine in Rush Medical College. W. B. Saunders & Company, Philadelphia, New York and London.

Dr. Bridge's book is recast from lectures delivered at Rush Medical College, Chicago, and is a worthy contribution to our American observations on tuberculosis, besides being thoroughly representative of our practical methods of diagnosis and treatment of the disease.

One phase of the extremely practical way Dr. Bridge has of looking at details of treatment of tuberculosis can be appreciated very well from a quotation from his chapter on Sanatoria for Consumptives. "If every person," he says, "with pulmonary tuberculosis, could, from the very first, give up and not pretend to himself or to others that he is well, but settle down with patience and attention to the business of getting well, the proportion of recoveries would be greatly increased. The sanatorium life is conducive in a high degree to this good philosophy. It is attainable at home, but less easily. There the temptation to do all sorts of things, often begets an attempt to hide even the existence of tuberculosis, as though it were a disgrace like drunkenness or opium taking, to be spoken of only in an undertone and even forgotten by the patient." This places the modern theory of the treatment of tuberculosis in sanatoria in a better light and truer than any statement we have yet seen.

It is not so much the air or even the diet of the sanatorium as the regularity of life and the admission that all are taking care of themselves because of deadly disease that counts for health.

Surgical Diseases of the Kidney and Ureter. Including Injuries, Malformations and Misplacements. By Henry Morris, M.A., M.B., Lond., F.R.C.S., Fellow and Chairman of the Court of Examiners of the Royal College of Surgeons, etc. W. T. Keener & Co., Chicago.

These two volumes come very near to the ideal in the completeness with which they cover an entire province of surgery, and in the masterly manner in which the subject is handled. Twenty years ago, when the author published his "Manual on the Surgical Diseases of the Kidney," he was a pioneer in what was almost a new field, and there was great difficulty in obtaining information, owing to the scantiness of material published, but the two following decades have been marked by the utmost activity in this department of surgery, and it now requires a master hand to set in order the voluminous literature which has accumulated since the first nephrolithotomy was done in 1880. The development of the surgery of the ureter is of still more recent growth, since, prior to 1894 the number of papers on this subject might be counted on the fingers of one hand, while now they run up into the hundreds. The author has done a work of inestimable value in digesting this mass of information scattered through the literature of the world and presenting what it contains of value, illuminated by his own vast experience. With a work of such scope a detailed review is scarcely possible and a general indication of the plan of the book must suffice. Volume I. is devoted entirely to the kidney and contains 21 chapters considering the normal and pathological gross anatomy of the organ, its clinical examination, movable and floating kidney, injuries and tumors of the kidney, perinephritic extravasations and inflammations, suppurative and non-suppurative pyelophlebitis, renal and circumrenal fistula, and tuberculosis and syphilis of the kidney.

The first portion of Volume II is given up to renal calculi and minute descriptions of the technic of the various operations on the organ. In Part Two the ureter is discussed and its anatomy, injuries, inflammations, strictures, tumors, fistulæ, calculi, etc., described in 20 additional chapters, together with the technic of its catheterization and operation upon it. The former is a procedure the author strongly condemns as a routine diagnostic measure, as well as for the purpose of

treating hydro- and pyonephrosis and ureteral stenosis, owing to the unreliableness of the information it affords, the risks to which it exposes the patient, and the difficulties of execution attending it. The use of Harris' and the other newer vesical segregators does not seem to be mentioned, nor is the value of cryoscopy in determining the functional efficiency of the "other kidney" indicated. We have also been unable to discover any mention of decortication of the kidney for chronic nephritis.

The illustrations are nearly all original, and for the most part portray pathological specimens.

The Surgical Diseases of the Genito-Urinary Organs. By E. L. Keyes, A.M., M.D., LL.D., Consulting Surgeon to the Bellevue and Skin and Cancer Hospitals, and E. L. Keyes, Jr., A.B., M.D., Ph.D., Lecturer on Genito-Urinary Surgery, New York Polyclinic Medical School and Hospital. A Revision of Van Buren and Keyes' Text-book. Appleton & Co., New York and London.

This, the second complete revision of what was the first book in any language in which genito-urinary diseases and syphilis were grouped together brings the volume once more to the pre-eminent position it had so long occupied. In accordance with modern views, syphilis, which is a genital disease only in its commonest method of invasion, has been entirely eliminated, while the anatomical method of classification formerly adopted has been abandoned in favor of the more logical clinical system of to-day. Venereal diseases, as such, having been excluded, sexual and genital maladies have been relegated to second place and somewhat subordinated to the consideration of diseases of the urinary tract. Gonorrhea, however, is considered at great length and its complications in joints, the eye, etc., are treated with unusual completeness. We accordingly find that the first 650 pages are devoted to diseases of the urinary organs, including gonorrhea, while the diseases of the genital organs per se occupy the remainder of the book.

In their treatment of specific urethritis the authors rank themselves with the advocates of the irrigation method and employ the modified Janet technic suggested by Chetwood. Ureteral catheterization they consider still sub judice, but the descriptions of the technic of cystoscopy and the interpretations of its results are excellent and accompanied by a good plate portraying typical cystoscopic pictures. The Bottini operation is admitted to be a step in the right direction in the treatment of prostatic hypertrophy, but is open to the objection of being done in the dark and of invading a septic cavity without providing drainage. The preference is accordingly given to Chetwood's perineal galvano-prostatotomy, which is practically a Bottini operation done through a perineal section wound. This is considered the simplest and safest operation yet devised for the cure of prostatic hypertrophy, though for the larger glands it may have to be supplemented by suprapubic or perineal prostatectomy.

The work throughout bears the stamp of wide experience and thoughtful consideration of the literature and affords a thoroughly reliable and instructive guide for the practitioner and student. Even though an occasional statement, such as the remark that in performing suprapubic aspiration of the bladder "it is not necessary that the surgeon's hands be surgically clean," and the advocacy of the subcutaneous ligature of varicocele does not altogether harmonize with the views of the general surgeon, the book no doubt remains the most valuable and authoritative work on the subject in the language and will enjoy the distinction, rare in medical literature, of having guided the thought and practice of three generations of medical men.

## BOOKS RECEIVED.

*The* Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Felix. A Novel. By R. S. Hichens. 8vo, 431 pages. F. A. Stokes Co., New York.

Autobiography of a Thief. By H. Hapgood. Octavo. Fox, Duffield & Co., New York.

Protozoa and Disease. By Dr. J. J. Clarke. 8vo, 177 pages. Illustrated. Wm. Wood & Co., New York.

Gynæcology. By Dr. W. R. Pryor. 8vo, 380 pages. Illustrated. D. Appleton & Co., New York and London.

A Treatise on the Care of the Expectant Mother. By Dr. L. Howe. 12mo, 63 pages. F. A. Davis Co., Philadelphia.

Tumors, Innocent and Malignant. By Dr. J. Bland Sutton. 8vo, 556 pages. Illustrated. W. T. Keener & Co., Chicago.

Surgical Diseases of the Abdomen. By Dr. Richard Douglas. 283 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Post-Mortem Pathology. By Dr. W. H. Cattell. 8vo, 372 pages. Illustrated. J. B. Lippincott Co., Philadelphia and London.

Uric Acid in the Causation of Disease. By Dr. A. Haig. Sixth edition. 8vo, 947 pages. P. Blakiston's Son & Co., Philadelphia.

Diseases and Injuries of the Eye. By Dr. Arnold Lawson. Sixth edition. 8vo, 587 pages. Illustrated. Smith, Elder & Co., London.

International Clinics. Volume I. Thirteenth Series. 1903. Octavo, 306 pages. Illustrated. J. B. Lippincott Co., Philadelphia.

Organic Nervous Diseases. By Dr. M. Allen Starr. Octavo. 8vo, 751 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

The Praxis of Urinary Analysis. By Dr. Lassar-Cohn. Translated by Dr. H. W. F. Lorenz. 12mo, 58 pages. John Wylie & Sons, New York.

Reference Handbook of the Medical Sciences. Edited by Dr. A. H. Buck. Volume I. Quarto. 1,004 pages. Illustrated. Wm. Wood & Co., New York.

Syphonage and Hydraulic Pressure in the Large Intestine. By Dr. R. W. Leftwich. 12mo, 80 pages. Illustrated. William Wood & Co., New York.

A Manual of Surgical Treatment. By Drs. W. W. Cheyne and F. F. Burghard. Vol. VII. 8vo, 559 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Modern Materia Medica and Therapeutics. By Dr. A. A. Stevens. Third edition. 8vo, 663 pages. W. B. Saunders & Company, New York, Philadelphia and London.

A Surgical Treatment of Gastric and Duodenal Ulcers. By Dr. B. G. A. Moynihan. 8vo, 82 pages. Illustrated. W. B. Saunders & Company, New York, Philadelphia and London.

A Practical Application of the Röntgen Rays in Therapeutics and Diagnosis. By Drs. W. A. Pusey and E. W. Caldwell. 8vo, 591 pages. Illustrated. W. B. Saunders & Company, New York, Philadelphia and London.

Physiological Aspects of the Liquor Problem. Investigations made and under the direction of W. O. Atwater, J. S. Billings, H. P. Bowditch, R. H. Chittenden. Two volumes. Octavo. Houghton, Mifflin & Co., Boston and New York.

## ORIGINAL ARTICLES.

### ACUTE NON-SUPPURATIVE ENCEPHALITIS: WITH REPORT OF A CASE.

BY HARLOW BROOKS, M.D.,

OF NEW YORK;

ASSISTANT PROFESSOR OF PATHOLOGY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; CURATOR TO BELLEVUE HOSPITAL; PATHOLOGIST TO MONTEFIORE AND HARLEM HOSPITALS.

CASES of acute non-suppurative encephalitis are not commonly reported in medical literature. Strümpell well states it is an exceptional disease and that our information concerning it is scanty. For this reason I believe that the following observations are noteworthy since they introduce what appears to be a most typical example of this condition.

Personally I am not inclined to think the disease so rare as generally believed, and, I think, that we may safely paraphrase Strümpell's statement and more certainly say that the disease is exceptionally recognized, largely due to the fact that our information concerning it is scanty.

The symptomatology of the condition is so similar to that of many other diseases that doubtless clinical cases are not infrequently recorded as of other forms of disease. Furthermore, the gross lesions may be so slight as to throw no further light on the case, even after post mortem examination, as in the instance I am about to present. Microscopical examination, in at least a considerable number of instances is the only possible method for its certain detection, and it is necessary that these studies be thorough in order that the condition be definitely recognized.

It is generally admitted that a considerable number of cases recover, either wholly or partly, depending on the extent and the location of the lesions. Probably then, the disease is much more frequent than generally supposed, and that its reported rarity is partly due to the great difficulty of differential diagnosis and because most of the cases fall naturally into the care of the more or less sceptical practitioner, who, unless the case terminate fatally ascribes it most likely to "hysteria," or because in the fatal cases the post mortem investigations are not sufficiently thorough to clearly identify the condition.

It appears to me that one of our most serious errors in the consideration of the disease lies in our very narrow conception of its etiology. Why should we not accept as an etiological factor every agent which is able to set up inflammatory processes in other parts of the body, as in the liver or kidney? Considering the brain in the same broad pathological sense as we do these more fully understood organs, we may consistently enlarge the generally accepted etiology to include nearly all inflammatory excitors. Of such, toxic agents are doubtless the most frequent. Among the toxins we must include many chemical poisons, of which alcohol is doubtless the most frequent, metabolic poisons and those toxins produced by the growth or action of bacteria. To these agents may also be added the inflammation following traumatism. There is no reason why all these factors should not enter into the production of inflammation of the brain, as they do in inflammatory diseases of other parts of the body. Modern pathology cannot tolerate the narrow and entirely fantastic idea that inflammatory processes are always produced by bacteria or their products, and yet I find this absurd theory stated to be the only possible explanation for acute cerebritis, in the articles of men, writing but a few years ago, who certainly should have known better.

The lesions of acute non-suppurative cerebritis may be considered in the same broad light and will be found to be of the same general character as those of inflammatory disease elsewhere, remembering, of course, the special histological characteristics of the cerebral tissues. Bearing this in mind, it is quite unnecessary that we subclassify non-suppurative encephalitis as hemorrhagic or not, for as in all inflammatory disease, whether hemorrhage takes place or not, depends entirely on the degree of the process and to a certain extent on the location of the lesions. Probably the reason that the hemorrhagic stage is relatively much more frequently reported is that hemorrhagic extravasation takes place in the advanced cases where diagnosis is more certain and death more likely to occur, while the post mortem lesions are of so striking a character as to be clearly evident to the most casual observer. Where extravasation does not take place, diagnosis is more difficult, and complete or partial recovery is probably the rule, while the gross lesions are of so minute a character as to escape all except the most careful investigations. I have demonstrated this to be the case in two instances of the acute non-suppurative cerebritis of acute alcoholism.

Acute encephalitis may terminate in death if the disease involves part of the encephalon the perfect function of which is essential to life. The process may extend to the pons, cerebellum and to the medulla.

Complete recovery may take place if the cause of the process disappear or exhaust itself, and if the lesions already produced be not too extensive or situated in vital centers. In such cases more or less complete absorption of the inflammatory exudate probably takes place. This is of course less frequent where hemorrhagic extravasations have taken place.

On the other hand partial absorption only, may

take place and cicatrices of hyperplastic neuroglia mark the sites of the old inflammatory foci, with the result of more or less disability of the function of the involved portions of the brain. In these cases a picture somewhat resembling that of disseminated sclerosis may follow. Such conditions are not at all uncommon in chronic alcoholics, or after severe cases of insolation, as stated by Collins.

It has seemed wise to me to consider the disease in this very general way, hoping that I might thereby attract more attention to the fact that the pathology of acute non-suppurative encephalitis is identical to similar processes affecting other organs. For a detailed account of the minute changes the readers are referred to the many excellent articles on the subject and to the lesions well typified in the following case which I now wish to present.

*History.**—The patient was admitted to St. Vincent's Hospital, on Oct. 19, 1902. The history is as follows: Female, aged nineteen years; domestic. She has been a heavy tea drinker, otherwise negative as far as can be ascertained; family history is negative. Her previous history was obtained at her place of employment. The patient had been subject to headaches for a considerable length of time, also to "bilious" attacks, some of which came on at the time of the monthly sickness. She had such an attack preceding present illness by a day or so. She was rather dull mentally.

On the night previous to her entrance to the hospital, she was apparently as well as usual. She did not appear at her usual hour on the next morning, and was found in her room in an unconscious condition. A physician was summoned but he was unable to arouse her. The patient had been accustomed to dose herself with antikamnia to control her headaches, and a box of these powders was found in her room. Her condition on admission was: Temperature, 100.4° F.; pulse, 130; respiration, 40. Patient is unconscious. Respirations are stertorous. There is no muscular rigidity, no twitchings and no paralysis. In response to pin pricks the patient draws away the hands and feet. The patellar reflexes are absent. The pupils are moderately dilated and react somewhat sluggishly to light. (The pupils were said to be "pin point" when she was first discovered.) The patient is unable to swallow, and does not arouse to any of the usual forms of stimulation.

The heart and lungs are normal. There is edema of the extremities and Kernig's sign is absent. No tache is manifested nor rigidity of the neck.

October 21: Urinary examination gave specific gravity 1.018; trace of albumin present; no casts. Temperature since admission has varied from 100° to 101° F. There has been incontinence of urine, and bowels were moved in response to croton oil, otherwise the condition is unchanged.

October 23: Urine, 1.024; trace of albumin; a few granular casts; many red and white blood cells.

October 25: Patient removed to another ward. Nurse reports that patient's back is very red over the sacrum, the skin in this location is slightly abraded. Incontinence of urine continues, though the patient is regularly catheterized. Patient seems a little brighter. The temperature has gradually been rising about one degree daily since Oct. 21, and is 104° F. to-night; leucocytosis of 14,000; eight grains of urea per ounce of urine.

October 27: Yesterday the patient twice took two ounces of water by mouth, otherwise all nourishment has been administered by stomach tube. The pulse averages 130; patient put on "mixed treatment."

October 29: The patient moans a good deal at night. Temperature varies from 102° to 104° F.; pulse about 140.

October 30: The patient spoke once yesterday, otherwise there has been no change. She spoke again to-day; was very noisy during the night. Urine: 1.029; faint trace of albumin; few hyaline casts; five grains of urea per ounce. The amount of urine has averaged over 30 ounces in so far as can be ascertained. The bed-sore is rapidly getting worse. White blood cell count 20,000; Widal reaction negative.

November 2: Yesterday morning the patient spoke rationally, complained of headache and of pains all over. She moved the head and hands; knee-jerks still absent; Babinski reflex marked; spoke again to-day; takes nourishment by mouth; incontinence of feces since yesterday; patient very noisy at night; mixed treatment discontinued. Redness and edema over both mastoid processes, no discharge from ears, drum membranes are intact, and there is no rigidity of the neck. A bed sore is developing over the right heel, and the sacral bed-sore has sloughed to the bone.

November 6: Yesterday the foot-drop was marked. There was no muscular response to pin-pricks, nor does patient wince when pricked on the legs, but when she is pricked above the knees and on the trunk, she does. Her temperature is 102° to 105° F.; pulse 140-160. Patient is placed on bromides grs. xxx q.4.h.; moaning almost constantly. Despite cardiac stimulation the pulse became weaker and the patient died with a temperature of 106° F. at 1.30 P.M.

Blood cultures taken several days before death were reported negative. The patient had begun to menstruate several days after admission, which probably accounts for the presence of blood in the early specimens of urine. Examination of the eyes several days before death showed no ocular disease. A post-mortem examination was obtained shortly after death. The necropsy was conducted by Dr. Theodore Janeway, to whom I am indebted for the tissues of the case. No gross

* I am indebted to Prof. Hermarn M. Biggs for the history of this case, and for permission to include it in this study.

lesions were found. It was noted that the cerebral tissue was somewhat lighter than normal in color, and its consistence was perhaps slightly increased. The protocol is not incorporated in this study, since its findings, bearing on the neurological symptomatology, are entirely negative.

Immediately after removal from the body the tissues were placed in 3 per cent. formalin solution. They were subsequently removed to appropriate fluids for the methods utilized in this study.

*Microscopical Examination.—Cerebral Cortex:* (Left precentral lobule). The lymph spaces of the pia-arachnoid are greatly dilated and contain a serous exudate in which lymphocytes are abundant. These cells have also infiltrated the stroma of the membrane. Connective tissue cells are numerous, and their nuclei show many evidences of proliferation. The blood vessels of the membrane are moderately congested, but their walls are not thickened and they are otherwise in normal condition, except that several of them contain masses of antemortem clot. A few small *Corpora amylacea* are found just beneath the pia-arachnoid and in the cortical tissue. They are also present in the membrane, but in less number. The outer layer of the cortex shows considerable fine granular disintegration, apparently from maceration by the meningeal effusion.

The blood-vessels throughout the cortex and in the subcortical white matter are much congested. Their walls are not thickened, but the perivascular lymph space is almost universally dilated; the lymph channels independent of the blood-vessels are also generally dilated. There are a few small oval or circular areas of lymphocyte infiltration scattered throughout the cortex, they seem to have no definite location, but are usually associated with a patch of unusually highly cellular neuroglia.

The layer of tangental nerve fibers shows a considerable number of fibers which exhibit large varicose swellings, sometimes of very large size and separated by narrow constrictions. Other fibers have become entirely broken up and their sheaths contain large clear vacuoles, indistinct lines of granules, or entirely refuse the stain. *Corpora amylacea* are found in this layer, but they are infrequent and of small size. Otherwise the molecular layer of the cortex shows nothing except the general lesions already mentioned. (Hematoxylin and Eosin, Pal-Weigert, Marchi.)

The layer of small pyramidal cells shows no gross ganglion cell alteration, no distortion, shrinkage or disintegration. Frequent cells, however, exhibit alterations in the chromophilic plaques (Nissl's methylene blue), and in some cases the nucleus is also altered in its appearance. The most frequent change appears to be a tendency toward chromatolysis, but occasional cells show the chromatic substance broken into small, very highly staining masses.

The ganglion cells of the large pyramidal cell layer (Nissl's stain) show more marked changes. Some of them are shrunken and respond diffusely to the stain, showing none of their finer normal structure, while others exhibit no variation in general form, but manifest cytoplasmic changes. These consist most commonly of a general chromatolysis, sometimes affecting both cytoplasm and nucleus, but generally seen only in the protoplasm. Another common form of degeneration, probably a less marked type of that just mentioned, is a breaking down of the plaques into a fine, slightly chromatic detritus. In the less marked stages the general outline of the normal chromatic arrangement is still seen but it has failed to respond to the dye. Wherever the cell protoplasm is degenerated, like changes are generally also present in the processes of that cell. In some places distinct spindle-shaped swellings of the neurit and dendrites are present. A considerable percentage of the cells show a tendency of the nucleus to wander toward one side of the cell. Other types of degeneration are evident in these cells, but those mentioned are most frequent. Lymphocytes are found here and there in the pericellular space, sometimes pressing upon the ganglion cell.

The white matter beneath the cortex, representing the fibers from these areas, shows many pathological alterations. One of the most remarkable of these consists of occasional areas in which active proliferation of the neuroglia is present. They vary from 1 to 2 mm. in diameter. In these places many large oval or round cells are found, closely packed together, intermingled with lymphocytes and neuroglia cells. These abnormal cells are about the size of an eosinophilic leucocyte, are usually mononuclear but occasionally contain two nuclei and their cytoplasm is finely granular. The distribution of their chromatin indicates that they are dividing rapidly. They appear like endothelial cells but probably are of neuroglial origin. About these patches of infiltration the invading cells gradually fade off into the tis-

Fig. 1.

sue becoming more and more scattered, so that no marked line of extension is present. Many of the lymph channels in this region of the brain are dilated, or contain the remains of an exudate apparently of serous character. *Corpora amylacea* are also found in various stages of formation, but they are not numerous. Numerous degenerated nerve fibers are demonstrable in these areas. (Pal-Weigert, Marchi.) The degenerations are apparently of somewhat recent origin, and many of the degenerated fibers incompletely retain the Pal-Weigert stain.

*Anterior Portion, Left Inferior Frontal Gyrus* (Marchi's method).—Changes similar to those described in the precentral lobule are present, but

Fig. 2.

Microphotograph. Objective Leitz No. 6. Ocular No. 3. Area of cellular infiltration in subcortical tissue of left precentral lobule. Thick section. Stained in hematoxylin eosin.

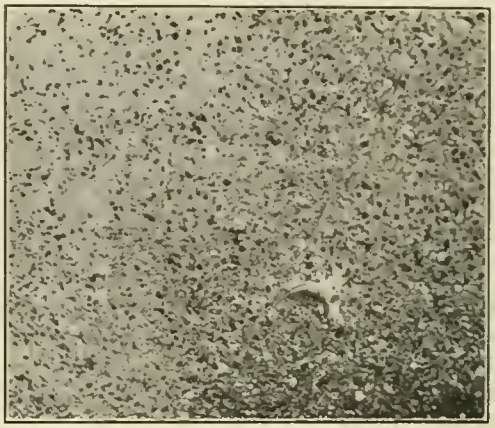
the alterations are of very much less marked degree and the number of degenerated fibers in the subcortical white matter is small, only five or six being seen in each Zeiss "D. D." field.

*Left Superior Temporal Gyrus* (Marchi's method).—Degenerated fibers are more frequent in these sections than in those of the previous gyrus, but they are still infrequent. The lymphatic and vascular lesions are also more marked, but much less so than in the precentral lobule.

*Left First Occipital Gyrus* (Marchi's method).—Degenerated fibers are abundant, but are less numerous than in the first lobule examined. The other lesions are present in corresponding degree.

*Left Internal Capsule.*—Small areas of cell infiltration, similar to those described above are found in the tissue of the nuclei bordering on the internal capsule. Some of the larger-sized vessels passing through the internal capsule are surrounded by quite marked infiltrations of small round cells. With these are a few polynuclear cells and in the surrounding tissue a few plasma and other cells similar to those of the other infiltrated areas. *Corpora amylacea* are numerous about the lymph spaces, some of them are of large size and lie within the clefts. Many of the fibers in the internal capsule are degenerated, and are

Fig. 3.



Microphotograph. Objective Leitz No. 3. Ocular No. 3. Degenerated fibers anterior genu, left internal capsule. Marchi's method.

limited to no particular part of the tracts but are scattered throughout. (Pal-Weigert, Marchi.)

*Cerebellum.*—The membranes of the cerebellum show the same changes as those of the cerebrum, but the infiltration is not so marked. A few large corpora amylacea are present about some of the larger meningeal vessels and in the outer portion of the molecular layer. The blood-vessels of the cerebellum are congested as in the cerebrum, but the dilation of the perivascular lymph spaces is not so marked here as there and the lymph channels in other parts of the tissue are normal.

Many of the Purkinje cells show degenerative cytoplasmic alterations, although all the ganglion cells are free from the grosser pathological changes. The most frequent cytoplasmic lesion (Nissl's stain) consists of a partial breaking up of the plaques into a fine, partially chromatic dust, while the general outline is still evident in most instances; in some cases the remaining fragments are hyperchromatic. A good many of the nuclei in the most altered cells show a chromatophilia. The alterations mentioned generally extended into the cell processes, while the large ganglion cells of the granule layer show very similar protoplasmic changes, but the granule cells show no apparent lesion.

The fibers in the white matter of the cerebellum exhibit nodosities or swellings at various parts of their course, but the degenerations are not advanced or general. (Pal-Weigert, Marchi.)

*Pons.*—The blood vessels throughout are considerably congested, but no areas of extravasation are present. The perivascular lymph spaces show no dilation but the independent lymph spaces show occasional dilations, though nowhere so marked as in the cerebrum.

*Corpora amylacea* are quite numerous, particu-

larly along the floor of the fourth ventricle, and among the fibers of the pyramidal tracts.

Many of the fibers in the pyramidal portion of the pons show extensive and quite general degenerations. (Pal-Weigert, Marchi.)

No sections were stained especially to ascertain the condition of the ganglion cells of the ventricular floor, but by ordinary methods no lesions are evident.

*Medulla Oblongata.*—The blood vessels are quite universally though but moderately congested, and some of them are surrounded by an exudate of small round cells, never very extensive. The perivascular lymph spaces are usually dilated, but not extremely so. *Corpora amylacea* are present and are most numerous just beneath the floor of the ventricle, in the pyramids and particularly just beneath the membranes. The membranes of the medulla show the same changes as were noted in those of the encephalon. One small area on the left side, in the floor of the ventricle, shows a patch of infiltration, but without pus formation. Except for the general perivascular infiltration no direct evidences of inflammation are found.

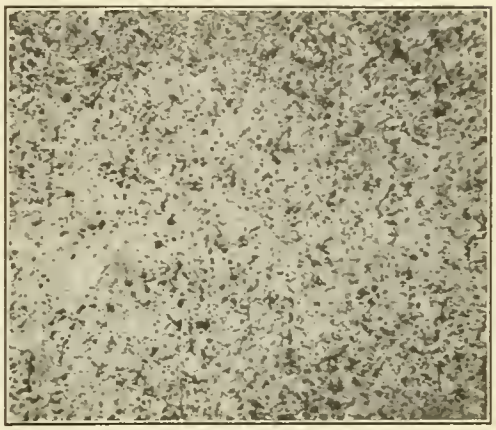
From 40 to 50 per cent. of the fibers in the pyramids of the medulla are degenerated, as shown by the Marchi method; the degeneration is much less apparent in sections stained by the method of Pal-Weigert. The cerebellar peduncles also show quite a number of degenerated fibers, but the degeneration here is by no means general. The fibers in the fillet are normal, but a few degenerated ones are seen in the lateral cerebellar tract. None of the fibers from the *Corpora dentata* or of the other transverse tracts are degenerated.

No gross alterations are present in the ganglion cells of the nuclei of the cranial nerves, situated in the floor of the fourth ventricle, but sections low down in the medulla show pronounced cytoplasmic alterations in the cells of the nucleus gracilis and cuneatus (Nissl method). These changes consist of various degrees of chromatolysis affecting both cytoplasm and nucleus in the most pronounced cases and in nearly all instances most extreme in the central portions of the cells. The plaques are much disintegrated in the most extreme examples, but in other cells are not broken up but simply stain faintly or exhibit a very finely granular condition. There is no cell shrinkage or nuclear eccentricity.

*Spinal Cord* (Cervical Region).—The membranes of this portion of the cord show a general small round-celled infiltration of slight to moderate degree. The blood-vessels are moderately congested, but considerably less so than those of the cerebrum, but the lymph spaces about the vessels and nerve cells and those of independent distribution are generally dilated.

There is a general and almost complete degeneration of the fibers of the direct and cross pyramidal tracts. This degeneration has not become of sufficient standing to show distinctly with the Pal-Weigert stain, but is very evident in sections prepared by the Marchi method. There are, in addition, a great many degenerated fibers

Fig. 4.



Microphotograph. Objective Leitz No. 3. Ocular No. 3. Degenerated fibers in right cross pyramidal tract of cervical spinal cord. Marchi's method.

in the lateral cerebellar tract and isolated degenerated fibers are also seen in the mixed lateral, and posterior zones, particularly in their peripheral portions.

The lymph spaces about the ganglion cells, especially those of the anterior horns, are dilated, but there has been no shrinkage or other gross alterations of those cells except for a frequent tendency toward eccentricity of the cell nucleus. Many of these cells, however, show quite pronounced cytoplasmic alterations (Nissl method). One of the most common of these, is a clumping of the chromatic material into large irregular masses, either in the center or in the peripheral portions of the cell. The spaces between these clumps are often filled in with fine granules of slightly chromatic material. Many of the nuclei show chromatolysis of quite marked degree. Other types of ganglion cell degeneration are also found, probably due in part at least to post-mortem changes or those alterations which immediately preceded death.

*Dorsal Spinal Cord.*—The membranes of this part of the cord show relatively less exudation but the vessels of both the membranes and of the medullary tissue show much more marked congestion than in the cervical portion, as is generally the case, for the dorsal portion of the cord is particularly prone to congestion. The lymphatic dilatation is less marked than in the cervical levels.

The degenerations are of about the same extent and involve the same distribution as in the cervical cord, but the isolated fibers in the mixed lateral and lateral cerebellar tracts are rather more infrequent. The number of degenerated, though always isolated fibers in the posterior tract is, perhaps, greater than in the upper levels. The ganglion cell changes are like those of the cervical cord.

*Lumbar Spinal Cord.*—Meningeal exudation is less marked than in the previous levels and the congestion of the blood vessels is of about the same degree as in the cervical cord, considerably less than in the dorsal portion. The dilation of the lymph spaces is more marked than in the dorsal cord.

In this region the degenerated fibers are more strictly confined to the direct and cross pyramidal tracts, but there are also a good many isolated degenerated fibers in the antero-lateral tracts, those in the posterior tracts are less frequent than in the cervical or dorsal cord.

Ganglion cell degeneration is much less marked in this region, but where present is of the same character as that found above. Nuclear eccentricity is less pronounced than in the upper levels.

*Lumbar Posterior Root Ganglion.*—There is no inflammatory infiltration about or in the ganglion. A good many of the ganglion cells show more or less shrinkage, but there are no other gross changes. The capsular cells of the lacunæ are in normal condition, and exhibit no tendency toward proliferation.

The cytoplasmic condition of the cells shows a considerable variation. Some of them appear perfectly normal (Nissl stain), but others exhibit a finely granular disintegration of the plaques, generally with proportionate chromatolysis, but a few cells show peripheral chromatophilia. The nuclei are apparently normal throughout.

*Sacral Spinal Cord.*—The meningeal exudation is very slight and the dilation of the lymph channels much less pronounced than in the other portions of the medulla spinalis. The degenerations are limited almost exclusively to the small areas representing the cross and direct pyramids. Isolated degenerated fibers in the other tracts are almost absent.

Ganglion cell degenerations are of much more limited extent (relatively) than in the previously considered levels of the cord—nearly all the cells are normal.

Microscopical examination of the tissues of the heart, liver, spleen, kidneys and pancreas showed no marked characteristic or significant changes.

The chief lesions of the central nervous tissues may be summarized as follows:

1. Cerebrospinal meningitis, probably secondary to cerebritis and of the "cellular" type as described by Delafield and Prudden.

2. General non-septic cerebritis affecting all parts of the cerebrum, but most marked in the cortex and particularly so in that of the motor areas. The disease is characterized pathologically by perivascular round-cell infiltration, dilation of the lymph spaces and by areas of neuroglial proliferation. The changes are further identified as inflammatory by the presence of occasional plasma cells.

3. Degeneration of many of the ganglion cells of the cortex. From the character of the lesions of these cells it is inferred that in most cases the changes have been of recent origin. Possibly some are post-mortem alterations.

4. Degeneration of many of the fibers arising from the large pyramidal cells of the cortex, most marked in those derived from the motor areas.

5. Diffuse degeneration affecting many of the fibers passing through both internal capsules.

6. Inflammation of the tissues of the cerebellum, of much less marked degree than in the cerebrum, but apparently of the same character and accompanied by similar, but much less extreme changes in the cells and fibers.

7. Degeneration of many of the descending fibers of the pons and medulla.

8. Degeneration of the chief descending tracts of the spinal cord with degeneration of occasional fibers in ascending tracts, possibly aberrant descending fibers.

9. Slight, probably secondary cytoplasmic degeneration of the ganglion cells of the anterior horns of the spinal cord.

In brief, we are dealing with a diffuse non-suppurative inflammation of the brain, most marked in the subcortical motor areas, with the resulting degeneration of those axis cylinder processes which extend into the spinal cord and which have their origin in the involved portions of the cortex.

Our examination has demonstrated clearly that the case is one of organic and not functional disorder, and the pathological findings satisfactorily explain the symptomatology of the case.

As to the origin of the disease, however, nothing is explained. From the character of the changes in the tissues and from the bacteriological examination of the blood, I think that we are safe in assuming that the cause was not infection.

The almost inevitable conclusion must be, unless some additional facts in regard to the case are discovered, that the lesions are of toxic origin. This toxin may perhaps have been of bacterial origin, for instance, it is stated that like conditions have resulted in influenza. It may have been of metabolic formation, or possibly some drug introduced in toxic doses. It has been noted in the history that the patient was in the habit of taking various headache powders, and it is possible that these may have caused the cerebritis, though I have been unable to find any drug, excepting alcohol, and possibly morphine, which are recognized as inducing alterations like those found in this case. Experiments are now under way by means of which we hope to prove or disprove this possibility.

---

**Diagnostic Value of Lumbar Puncture.**—Greater care in drawing conclusions from the data obtained by lumbar puncture in cases of cerebral disease, is urged by G. Orgelmeister (Arch. f. klin. Med., Vol. 76, No. 1-3). In fifteen undoubted cases of tuberculous meningitis, in which this procedure was employed, the formation of floculi in the fluid, considered by many authors to be a distinct characteristic of the disease, was entirely absent in four. The finding of the tubercle bacilli, is the only means of making an absolute diagnosis, and in suspected cases of localized cerebral disease, a positive bacteriological result can form the only contra-indication for operative interference.

## THE FORM OF THE URETER.

BY BYRON ROBINSON, B.S., M.D.,
OF CHICAGO.

The ureter is not a uniform calibered tube but consists of ureteral dilatations and constrictions. Calculi lodge at the ureteral isthmuses or constrictions as well as at the turns of compromising flexions. Surgery should be performed at the ureteral dilatations on account of ample lumen and easier manipulation.

Fig. 1 illustrates the form of ten ureters distended with paraffin, demonstrating (*a*) the three ureteral dilatations, spindles (reservoirs) (2, 4, 6); (*b*), the three constrictions sphincters (3, 5, 7,) and (*c*) the spirality was noted while distending the ureters with melted paraffin, the free ureter would rotate from right to left about two circles.

Nos. 1 (left) and 2 (right). Man, age forty-six years. This pair shows the left calyces (1, 1) dilated and a well-developed pelvis (2). The left proximal ureteral isthmus (3) well marked and distalward located, the right (3) indistinct and elongated, less constricted. The left lumbar spindle (4) the most prominently developed and the more distalward located. The middle isthmuses (5, 5) moderately marked. In each ureter two pelvic spindles (6, 6) exists. The distal isthmuses (7, 7) were less in lumen than the proximal (3, 3).

N. B.—The left ureter 1, presented 5 well-marked spinal ridges projecting in the ureteral lumen. All ureteral dilatations are more prominent in the left. The left ureter (1) was one inch longer than the right (2).

The left ureter (1) is complete, *i.e.*, it presents four calyces (1, 1), pelvis (2) ureter proper and the renal artery lying on the ventral surface of the

calyces and pelvis. The calyces and pelvis were the result of corrosion anatomy. Nos. 3 (left) and 4 (right) woman—. This pair shows well marked right calyces (1, 1), well-developed oval pelvis (2), and distinctly marked right narrow proximal isthmus (3). Prominent right lumbar spindle (4). The right middle isthmus (5) should be placed on a level with the left middle isthmus (5).

Two pelvic spindles exist in each ureter (6, 6). The right lumbar spindle is generally larger in woman than man. The distal isthmuses (7, 7) were larger in caliber than the right proximal (3).

No. 5. (left) lumbar spindle (4) and two short pelvic spindles (6, 6). No. 6 (right) shows short narrow proximal isthmus (3). Two large and one small lumbar spindle (4—), a narrow middle isthmus (5), a short well-marked pelvic spindle (6). Nos. 7 (left) and 8 (right); man, age forty-six years. This pair shows moderately developed calyces (1, 1), double armed slightly developed rounded pelvis (2, 2). Marked but distally located proximal isthmuses (3, 3). Short but marked lumbar spindles (4, 4). Moderately marked middle isthmus (5, 5). Two unequally sized pelvic spindles, on each side (6, 6). Distal isthmuses (7, 7) about equal in lumen to the proximal (3, 3). Nos. 9 (left) and 10 (right), woman, age forty-nine years. This pair shows moderately developed flattened right pelvis (2). Indistinct elongated proximal ureteral isthmuses (3, 3). Slightly developed left lumbar spindle (4) but more marked right one (10). The middle isthmus is but slightly marked on left (5), on the right more marked. The right (10) shows two large and one small pelvic spindle (6, 6). The left ureter (9) shows one pelvic spindle (6°). The distal isthmuses (7, 7) are less in caliber than the proximal.

I removed the ureters here illustrated at post mortems, through the courtesy of Prof. W. A. Evans, immediately injected them with melted paraffin, subsequently dried and painted them white. Dr. William E. Holland executed the photograph. The pairs of ureters are valuable for comparison.

## A SIMPLE AND RAPID CHROMATIN STAIN FOR THE MALARIAL PARASITE.

BY FRANCIS CARTER WOOD, M.D.,
OF NEW YORK;
INSTRUCTOR IN CLINICAL PATHOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

THE recent increase in our knowledge of the alterations in the morphology of the blood which occur in disease is largely due to the simplification in the technic of staining which has been so pronounced in the last few years. As a result of this technical simplicity the clinician has at his disposal the means for the rapid and easy preparation of suitably stained blood smears, and in consequence a large amount of material has been observed and recorded. Believing that any improvement in the technic of blood staining which tends toward ease and simplicity of manipulation may be of use to students and teachers of blood morphology, the writer has felt that certain methods which he has found valuable may not be without interest.

The first experiments were based upon an accidental observation that old alcoholic solutions of the eosinate of methylene blue in the form devised by Jenner[1], and republished as an independent discovery by May and Grünwald[2] three years later, are capable of giving a fairly good chromatin stain in the young forms of the malarial parasite. The methylene blue component of the dye is apparently altered by the alkali dissolved from the glass of the container and a portion is transferred into what has been shown by Michaelis[3] to be closely allied to, if not identical with, methylene azure. If a slide containing malarial parasites is stained with this ripened Jenner dye and slowly washed off in distilled water, a moderate chromatin stain is produced showing the larger nuclear masses of the ring forms and also the reddish granules occasionally seen in the bodies of the lymphocytes. Such a selective stain is not, however, produced on smears which are dropped quickly into distilled water or washed off under the tap, for the peculiar quality of the stain which causes it to color the chromatic substance appears only when the dye is in a watery solution and depends perhaps upon some phenomenon of dissociation of the components of the salt in water. The alcoholic solution is not dissociated, and its pure blue color is immediately altered to a reddish purple by the addition of water with the formation of an abundant precipitate.

A number of observers have devised staining combinations in which advantage has been taken of the solubility of the eosinate of methylene blue and methylene azure in methyl alcohol and the power which the mixture has to produce a chromatin stain when diluted with water, among them Leishman,[4] Wright,[5] and Reuter.[6] The latter uses the alcoholic stain only as a stock solution to be diluted with water before use; the others fix and stain at the same time in the methyl alcohol in which is dissolved the precipitate formed by mixing eosin and methylene blue, containing some methylene azure produced by previously heating the methylene blue with a dilute alkali.

To obtain a chromatin stain with the Leishman or Wright mixtures it is necessary to dilute the fresh alcoholic dye with distilled water after it has been in contact with the smear for a few minutes, and allow this combination to act for from three to ten minutes upon the blood spread, but the precipitate which immediately forms when the mixture is diluted is very likely to be deposited upon the smear and give rise to annoying artefacts which can only be removed by treating the slide with strong methyl alcohol and repeating the staining process. The writer has also found after a considerable experience with both methods that it is difficult to obtain constant results even when using smears of the same age and thickness and the same preparation of the stain.

The Wright stain especially, when it is successful, affords an exceedingly instructive smear and demonstrates the chromatin granules of the malarial parasite sharply and well; but as a stain for general class use or for preparing large series of slides for the use of students, the writer has not found it as useful as a much simpler method, using the purified methylene azure as obtained from Grübler. The use of the pure dye, the preparation of which we owe to Giemsa,[7] obviates the uncertain and tedious process of preparing

the methylene azure solution by the treatment with alkalies and gives the staining method much of the certainty and simplicity of the old eosin and methylene blue stain so much used before the introduction of the Ehrlich and Jenner combinations. Giemsa and Nocht[8] recommended staining slides for some time in a dilute mixture of the eosin and methylene azure, a method which is necessary for staining old slides, but unnecessary for fresh preparations. The writer has found that while this eosinmethylene azure combination will stain slides which are from two to three years old and produce under these circumstances an excellent chromatin stain without any of the diffuse bluish color which is usually seen in preparations of slides over one month old, a fact of considerable advantage, especially for the purpose of restaining faded demonstration slides or old-type specimens which show some especially interesting features, that an equally good stain of fresh specimens can be obtained as follows.

Fix the preparation for one minute in strong methyl alcohol, wash off in water and stain the slide for a few seconds with a one-tenth-per-cent. aqueous solution of yellowish eosin. The surplus of the eosin solution should be poured off and a few drops of a one-fifth-per-cent. solution of methylene azure poured over the slide. The staining will be complete in from one-half to one minute and the slide may be washed with distilled or tap water and dried with blotting paper. The best paper for this purpose is a thick, smooth-surfaced variety used by photographers to dry prints. The close grain and hard finish of this paper prevents the deposition of any fiber on the surface of the blood smear.

A longer treatment with the azure solution produces a deeper chromatin stain, a shorter treatment produces a stain of less intensity. If a stain of any particular depth is required the whole process may be easily observed under the microscope, selecting a group of leucocytes as a guide. The stain will be seen to gradually color the nuclei of the polynuclears a deep red, and at the proper point the neutrophile granules will be easily visible with a good four mm. dry lens. At the same time the nuclei of the large and small lymphocytes assume a deep red color and the cell bodies of the large forms color a pale blue, while the bodies of the small cells will be a deep blue. At this stage of the process the malarial parasite is of a pale blue color with deeply red chromatin granules. If the methylene azure has remained in contact with the smear but a short time the red cells will be of a bright pink color, but if the staining is prolonged the red cells become bluish or greenish in color. After prolonged staining with the azure the color of the neutrophile granules generally fades and the bright pink of the eosinophiles is replaced by a bluish tint. For general purposes, therefore, it is best not to stain the slide too long with the methylene azure. By increasing the strength of the azure solution up to one-half of one per cent. the staining process with that substance may be shortened to a few seconds, but overstaining is much more likely to take place. If the blue color of the red cells is very marked the excess may be removed by treating the smear for about one second with dilute alcohol, say of about 80 per cent., and then washing off in water. Some color is likely to be removed from the nuclear chromatin by this process of decolorization, and the red of the finer chromatin particles of the gametes loses its sharp outline or may be entirely extracted so that the alcohol treatment is not to be recommended for general use. Thus by the use of this process a good chromatin stain can be obtained in three minutes after the blood smear is secured. Such preparations may also be used for differential counting, though for general purposes the Jenner mixture is preferable because the eosinophile and basophile granules are on the whole more characteristically stained. The large and small lymphocytes on the other hand are better demonstrated with the methylene azure. The large mononuclears cannot be constantly separated from the large lymphocytes by any of the dyes containing methylene blue, and are best classed with the large lymphocytes. Beginners may mistake the blood plates, which often lie in depressions in the red cells, for malarial parasites, especially as they stain red with the chromatin dyes. The distinction must be made by the differences in morphology. The blood plate is not sharply outlined and the nuclear substance is in the form of an indistinct mass not surrounded by a clear zone, while the small ring-form of the malarial parasite is very sharp in its outline, as is also the chromatic substance, the latter being surrounded by a clear zone and beyond this by the blue ring of the body of the parasite.

The staining of old preparations cannot be achieved in a satisfactory manner with any of the usual blood stains except the Ehrlich triacid, which does not demonstrate the malarial parasite. By the use of dilute mixtures of eosin and methylene azure, as suggested by Nocht, it is possible to obtain perfect stains from slides which are months or even years old. The older the slide the more dilute must be the stain, and the longer it must remain in the staining fluid. Two methods may be used. The slide should be fixed for at least half an hour in methyl alcohol. Then it may be allowed to remain for from four to twenty-four hours in a strong mixture containing about 50 c.c. of a one-to-a-thousand methylene azure solution to which has been added from two to five c.c. of a one-to-a-thousand aqueous eosin. The mixed solutions are best placed in a Coplin jar and the slides allowed to stand vertically. As a rule, a precipitate is not formed, but if any should form it is not likely to be deposited on the surface of the smear. In case such a precipitate should be deposited on the smear it can be removed by dipping the slide in strong ethyl alcohol for a few seconds and then washing off in water. Slides stained in this manner are usually much overcolored and must be decolorized in 80 per cent. ethyl alcohol and then washed in water. By this means the excess of the blue dye is removed and

the chromatin particles in the malarial parasites are well brought out. The same result may be obtained by staining for from twenty-four to thirty-six hours in the above mixture diluted about five times with distilled water. It is not usually necessary to decolorize slides stained in this dilute mixture. The solutions when once mixed can be used to stain four or five series of slides, after which the color is exhausted.

## THE CHOICE OF TECHNIC IN OPERATING UPON PROSTATIC OBSTRUCTION.

BY CHARLES H. CHETWOOD, M.D.,

OF NEW YORK.

PROFESSOR OF GENITO-URINARY SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON TO BELLEVUE HOSPITAL.

I HAVE assembled in this brief article the salient facts in the histories of cases operated upon by perineal galvanoprostatotomy, some of them of quite recent date and others of long standing, in order that, from the record of these cases, the immediate and more or less permanent effect of operation may be noted; and the object of this writing is to demonstrate the fact—or rather to submit evidence bearing upon it—that this operation is applicable to a large proportion of cases in which it is found necessary to remove obstruction to the bladder outlet for the relief of vesical insufficiency when caused either by prostatic hypertrophy or the analogous condition —contracture of the neck of bladder. I believe that the most important element in the causation of vesical insufficiency is the mechanical obstruction at the urethral orifice, and that to accomplish its satisfactory relief the most essential requirement is removal of the obstruction. This obstruction may be an orificial hypertrophy, or a fibrotic contracture, a retro-prostatic lip with a vesical pouch beneath, a greater development of this isthmus in the form of a middle lobe, a unilateral or bilateral enlargement of the prostate obtruding upon the urethra, or a combination of any of these formations. Cystitis may sooner or later supervene and become chronic. It greatly aggravates conditions and favors the development of secondary changes in the bladder wall in the form of muscular atrophy and fibrous infiltration.

The day is not far off—if it has not already dawned—when surgeons will unhesitatingly advise sufferers from permanent prostatic obstruction to submit to early operation rather than await the development of serious secondary conditions, or accept the artificial and not uncheckered existence incident to so-called catheter life.

As recently as two years ago, the weight of opinion expressed at the meeting of the American Association of Genito-Urinary Surgeons favored palliative treatment in the majority of cases. During the past two years, however, much active work has been done along the line of operative procedure; and so many surgeons have demonstrated the practicability of the various operations performed by them, even in cases of an advanced and apparently hopeless character, that there is now evidence of a decided leaning toward operation in the early as well as the late stages of this morbid condition of mature age. This being demonstrated, as one writer aptly expresses it, "Attention should now be directed to perfecting the operative technic, and to convincing the general practitioner into whose care these cases first come that prolonged catheterism even under the most favorable circumstances, is a dangerous practice."

According to the statistics of Sir Henry Thompson, about 33 per cent. of men beyond the age of fifty-five years are subjects of enlargement of the prostate, while not over 15 per cent. ever suffer from symptoms. Thus 85 per cent. of those having hypertrophied prostates experience no inconvenience therefrom, since the direction of the growth is not such as to interfere with the bladder function.

All observers agree that the size of the enlargement bears no relation to the severity of the urinary distress produced. The orificial hypertrophy or fibrous contracture may be the cause of the most intense and uncontrollable symptoms; the small middle lobe may produce complete retention of urine; while a prostate as large as a cricket ball, weighing 10½ oz. and almost completely filling up the cavity of the bladder—as in one of Mr. Freyer's cases (*British Medical Journal*, Nov. 8, 1902)—may be accompanied by only three ounces of residual urine.

Confronted with these facts it is difficult to believe that, in order to relieve the bladder symptoms which occur in only 15 per cent. of the cases, it is essential to remove the entire gland—or in many instances, more than a very moderate portion of it. Numerous reports of middle-lobe enucleation, of partial extirpation of hypertrophied tissue by knife, scissors, with the prostatic rongeur and with the cautery, which have been followed by ideal results, give weight to this view.

Generally speaking we meet three classes of cases suffering from vesical insufficiency, the result of obstruction at the urinary outlet:

1. Those in which there exists one or the other of the different forms of obstruction without cystitis.

2. Those in which there is more or less long-standing chronic cystitis, producing that train of symptoms collectively called "prostatism."

3. Those cases in which the mechanical obstruction, as well as the chronic cystitis, has existed so long that secondary changes involve the bladder, beginning with hypertrophy and ending in atrophy, contraction of the bladder wall, and decided diminishment in the bladder capacity.

Briefly then, in the first class there is simple obstruction, in the second obstruction with inflammation behind it, in the third obstruction, inflammation and secondary degenerative changes. The object of operation in the first class is to remove the obstruction, and in removing it to do so permanently. In the second class, the same object is held in view with the further purpose of draining the inflamed viscus. In the third class, nothing more can be done than is done in the second; and it is sometimes not possible by means of operation to affect the advanced degenerative changes which occur late in these cases.

In order to accomplish the desired result by any operation, it is absolutely necessary to open the way at the vesical outlet, to lower the barrier, so that, if there be sufficient restoration of the lost tone of the bladder muscle, the organ will be able to empty itself completely. This may be accomplished by lobular enucleation of as much of the glandular structure as may suit the taste of the individual surgeon, or by galvanocautery incisions, which aim to burn a trough through the obstructing tissue and contracted orifice. It is quite frequent to find complete retention of urine, advanced secondary changes, and all the conditions peculiar to prostatic hypertrophy without any enlargement whatsoever of the gland, dependent upon orificial contracture of the bladder outlet of a purely inflammatory character; and this same condition is found in conjunction with prostatic hypertrophy. The removal of a large portion of the gland, without enlarging the orificial contracture and lowering the level of bladder neck, may be the cause of failure by operation to relieve bladder insufficiency.

Mr. William Freyer cites a case of complete vesical insufficiency without prostatic enlargement. The patient, aged eighty-four years, had been dependent upon the catheter for twenty-six years. Practically the entire amount of urine was voided by means of the catheter. No enlargement of the prostate was felt by the rectum. It was impossible to introduce a sound through the urethra, but the presence of vesical calculi was suspected. He opened the bladder with a view to removing both prostate and calculi. Two calculi, one inch in diameter each, were found, but, to his surprise, there was no intravesical enlargement of the prostate. With one finger in the rectum and another in the bladder, it was impossible to find any enlargement whatever of the gland. Nothing was done, except removal of the stones, and the result was no restoration of function.

The writer propounds two rather interesting questions in connection with this case: (1) Is it possible that prostatic atrophy succeeds enlargement, and if so, why did the patient not gain the power of voluntary micturition? (2) Was the case a sample of those one occasionally meets with, in which the patient enters on catheter life sometimes long before the age of prostatic enlargement, and if so, why did the patient not gain the power of voluntary micturition, where neither the enlargement of the prostate nor other tangible cause was found to account for this condition? I would answer by stating that contracture of the neck of the bladder is a frequent cause of vesical insufficiency and voluntary micturition will not follow operation unless the obstacle be removed.

Compare with the above case one which is almost a complete parallel to it.

The patient, an old gentleman, sixty-two years old, first appeared in Jan., 1890, complaining of great distress and tenesmus, and suffering from chronic complete retention of several years' duration, being entirely dependent upon the catheter. The presence of vesical calculi was determined with the Thompson searcher. A suprapubic cystotomy was performed. Two calculi, about the size of horse-chestnuts, were removed, and a third encysted stone in the region of the ureter as well. There was no intravesical enlargement of the prostate, and nothing further was done.

The patient made a good recovery from the operation; but there was no change whatever, so far as the vesical insufficiency was concerned.

In the fall of 1902, twelve years later, the patient again appeared; he having, during the entire intervening period, relied upon the catheter. Nov. 11, 1902, a perineal galvanoprostatotomy was performed by my colleague, Dr. Keyes, Jr. A dense contracture of the neck of the bladder was found; the prostate being absolutely normal. The contracture was incised by two galvanocautery incisions. The patient was out of bed on the seventh day and left the hospital on the eleventh day. Six months after the operation the patient continues to enjoy voluntary micturition, which was regained shortly after the operation, and he is able to empty the bladder down to about one ounce. The admirable result in this case is beyond criticism.

To-day the choice of operation may be said to lie between prostatectomy by lobular enucleation and prostatotomy by means of galvanocautery incisions. I shall not undertake to discuss the question of complete or incomplete prostatectomy, or of the relative merits of the supra- or infrapubic routes: it being understood that, by prostatectomy, I refer to the operation which, by avulsion, removes a greater portion of the enlarged gland than directly interferes with the outlet to the bladder.

The opinion of surgeons who are adherents of prostatectomy, regarding the operation of prostatotomy, seems to be that it is adapted to moderate growths, such as bar formation and orificial hypertrophy, and to early operation. By some it is thought preferable in the late stages of the malady, when the bladder is contracted and permanent degenerative changes exist, when the kidneys are involved and the general health of the patient is seriously undermined. The inference derived from such an opinion is that prostatotomy is less fatal than prostatectomy, which is undoubtedly the fact.

No thoughtful surgeon will declare that the mortality rate of prostatectomy is trivial. There is no doubt that under improved technic and in

good hands the mortality has materially decreased in the last year or so. It is variously estimated at the present day as being from 6 to 16 per cent., and I am inclined to believe that, taking an average of all well-known operators, it is nearer the higher than the lower figure. Alexander, whose special work in perineal prostatectomy has been an inspiration in this country to other surgeons, always held a conservative position in this particular and is not inclined to make light of the gravity of the operation performed by him. Of 31 cases reported there were three deaths, or about 10 per cent. William Freyer has up to recent date reported 31 cases of total prostatectomy by the suprapubic route. Of this number there were four deaths: two died of mania, one on the twenty-fourth day and the other in the third week, one died of urinary toxemia, and one on the eighth day very suddenly from what he considered to be a heat stroke; but the manner of death is very suggestive of pulmonary or cardiac embolism. There are two other patients who were operated on by him; but as he did not remove all of the prostate he fails to classify them with the other cases. In studying the detailed history of these fatal cases it is difficult to disassociate the operation from the cause of death.

Guitéras collected 152 cases of prostatectomy by various methods (Nov. 2, 1901, *Jour. Am. Med. Ass'n*), showing a mortality rate of $16^4/_{10}$ per cent.

Parker Syms reports 21 cases of perineal prostatectomy without a death, and thus contributes materially toward decreasing the mean rate of mortality.

In spite of the enthusiasm displayed by one class of surgeons for perineal and by another for suprapubic prostatectomy, there is ever present a reluctance to advise these operations, except in default of milder measures. Thus Dandridge (*N. Y. Med. Jour.*, Jan., 1903) refers to Murphy's method of removal of the prostate by the perineum as the operation which seems to accomplish complete removal of the obstruction with less dangerous disturbance to the parts involved than any of the other procedures yet suggested; but counsels more conservative measures in these words: "I am strongly convinced that the method of choice in the largest proportion of cases of hypertrophy is still the proper and judicious use of the catheter." Mr. William Freyer, one of the most ardent advocates of the suprapubic operation ("Stricture of the Urethra and Hypertrophy of Prostate," London, 1902) in the course of his lectures in which he describes and favors his operation of total extirpation of the gland suprapubically, thus expresses himself: "Holding as I do that in certain cases of this disorder operation is advisable, I have no hesitation in saying that, in the majority, the only advisable treatment is just and cleanly catheterism combined with careful, hygienic living." The habitual use of the catheter with its perils and discomforts is, nevertheless, an unsatisfactory expedient, and it is not in pace with modern surgical advance to rely upon so undesirable a resource.

Prostatotomy is an operation of lesser magnitude than prostatectomy, and if demonstrated to be safe and effective, the earlier it is employed the safer it is bound to be and the more satisfactory will be the immediate and ultimate results.

By performing prostatotomy by means of galvano-caustic incisions the operation is much simplified and convalescence shortened. The value of galvanocauterization in performing prostatotomy has been amply established. The operation is done either through the urethra (Bottini) or through a perineal wound (Chetwood). The selection of technic must be made by comparing the merits of the two methods.

Aside from the question of mortality, which, according to different observers, varies between 6 and 12 per cent., there are, to my mind, a number of insurmountable obstacles in operating by the Bottini method: the uncertainty of the nature of the prostatic growth, its size and conformation; the difficulty of determining the proper length of the incision, especially in the case of a soft prostate; the inability to verify results immediately, and consequently the necessity of performing repeated operations in some instances; the danger of postoperative hemorrhage and sepsis; the absence of vesical drainage. These objections are variously answered by the adherents of the operation, but have not been removed. I can understand that adroit manipulators of the instrument and expert cystoscopists become past-masters in the performance of the Bottini operation: and yet we read of such accidents as render the operation objectionable, even at the hands of these experts.

Freudenberg actually incised a fold of bladder with fatal results. Young states that death was caused in several instances by division of the membranous urethra on account of hemorrhage and extravasation. Too long an anterior incision has also caused a fatal issue and resulted in the abandonment of that incision. In one of Freudenberg's cases, the beak of the instrument burrowed through the rectum. Bangs, Guitéras and Meyer have cut into the membranous urethra, and in two instances the patients were saved only by prompt perineal section. It has been necessary to open the bladder above the bone to control severe hemorrhage soon after the operation, and later to turn out decomposed and septic blood clots.

Perineal prostatotomy with the galvanocautery I have found possesses all the advantages that may be claimed for cauterization and would seem to meet the objections raised against the Bottini method. Perineal cystotomy, which is the first step in the operation, permits an ante- and postoperative examination and affords complete and adequate drainage. I shall not give a description of the technic, having already done so on previous occasions.

Forty-five cases of various types have in all been operated upon by myself and my colleagues. The first 23 patients have been reported

before the American Association of Genito-Urinary Surgeons. The histories of these cases have been published in detail (*N. Y. Med. Record*, May 18, 1901; *N. Y. Med. Jour.*, May 31, 1902). I have been able to trace up many of these patients, and those heard from have maintained the improved conditions which were reported as a result of the operation.

There have been 22 patients subsequently operated upon. One was below forty years of age, and 4 between forty and forty-five years. Of the remaining 17 patients, one was fifty-one and one fifty-six, and the others between sixty-three and seventy-nine years old. Five patients were cases of contracture of the neck of the bladder as a result of chronic, refractory posterior urethritis. Five patients were cases of contracture of the neck of the bladder in men of mature age (between fifty-one and seventy-four years), all of whom had exhibited characteristic prostatic symptoms for from one to fifteen years. All of them had considerable residual urine; three of them complete retention, in one of whom it had existed for 15 years. Three patients presented a moderate enlargement of the prostate, combined with marked contracture of the neck of the bladder, their ages being sixty-five, seventy-two, and seventy-three years respectively. They had all complained of the characteristic symptoms of prostatism for a number of years. One patient had a median lobe, two patients bilateral enlargement with median growth; and six patients bilateral lobular enlargement.

In reviewing the results in the entire number of 45 cases, there are three recent cases still under treatment, and the outcome of operation can not be estimated, although they all promise well. There has been but one death directly associated with the operation; and this one, an old man with a fatty heart and generally septic, who died on the sixth day. One patient died seven weeks after the operation from renal insufficiency, he having had only one-half of one per cent. daily secretion of urea, or one-quarter of the normal output, before operation. From the fact that he lived five weeks in this condition, it does not seem that the operation precipitated the end. In another patient who died, the post mortem showed as the cause of death an enormous, old, pyonephrosis, with a pus sac as large as an infant's head, which was not recognized before operation on account of the symptoms having been entirely vesical. Another died without unfavorable symptoms connected with the seat of operation, but developed a general peritonitis from rupture of a duodenal ulcer, he having had intestinal symptoms for years previously. An exploratory operation revealed the condition and the post mortem confirmed it.

Of the remainder, this leaves 30 cases cured or materially improved, five partially improved, and three not improved two of which were tuberculous. All presented symptoms of more or less severe cystitis. Residual urine varied from three ounces to a pint in a large percentage of the cases. In only three cases of contracture was there none.

The results are measured by comparing the conditions before and after operation. In those cases which were recorded as materially improved or cured the symptoms of vesical irritability and the residual urine have disappeared or materially diminished, and the patients are generally satisfied with their condition. The catheter has been dispensed with in all but one case, and in this one there is evidence of returning voluntary urination.

As a result of experience in these 45 cases, I feel that the following conclusions are warranted:

That prostatotomy is less dangerous than prostatectomy; that it is the operation of choice in a large number of cases of prostatic obstruction, notably those of moderate glandular enlargement, orificial hypertrophy and contracture, in which the prime object is removal of the obstruction and depression of the bladder orifice; that galvanocaustic incisions, when combined with perineal cystotomy, accomplish satisfactorily the desired result, shorten the operation, and minimize its dangers.

---

## SO-CALLED "STOMACH-ACHE."

BY PAUL COHNHEIM, M.D.,
OF BERLIN, GERMANY.
Translated by
WILLIAM GRAY SCHAUFFLER, M.D.,
OF LAKEWOOD, N. J.

In but few departments of human pathology is the physician so dependent on the patient's own history of his symptoms, as in the domain of diseases of the abdominal organs, if he desires to make an exact diagnosis and institute a rational line of treatment. While the oculist, the gynecologist, the dermatologist and the genito-urinary surgeon require only a few subjective statements from their patients and rely almost entirely on their own objective findings to locate the seat and nature of the disease, the diagnosis of chronic diseases of the viscera, as of those of the nervous system, requires thorough inquiry into the history and careful, critical weighing of the patient's statements. He who understands how to weed out the unimportant features from the complaints and stories of a given patient, and emphasize sufficiently the essentials, without falling into the errors of a "snap-diagnosis," will often find it easy to make a correct diagnosis from the history alone.

One symptom common to the most varied forms of internal diseases, and reappearing with almost malignant constancy is what is commonly called "stomach-ache" (Magenkrampf). Under this name the layman sums up all colicky pains which

*This short paper by Dr. Cohnheim appeared in the *Deutsche-Medicinische Presse*, No. 12, Vol. 28. Dr. Cohnheim's position in Berlin, where he was for some time Boas' assistant, and now conducts a large clinic of his own, is such that anything from his pen bears the weight of careful thought as well as ripe experience.
W. G. S.

make themselves felt in the epigastrium or its neighborhood, whether, as we shall see further on, they have their origin in the stomach, the colon, the liver, the heart, the uterus, the intercostal spaces, or elsewhere.

In discussing this symptom we shall for the present separate from the unpleasant sensations which may occur in the epigastrium, all such as partake of the character of pressure, or at least of painful pressure. Almost every sufferer from stomach trouble will complain of "stomach-ache." Our first task is to find out whether this "stomach-ache" represents real pain, or only an unpleasant sensation of pressure, tension, fulness, burning or eructation, especially after taking food. Many patients will admit at once that they have never had real pain, even when their complaints have been of from ten to twenty years' duration. None of these cases concern us, for they either belong under the head of nervous dyspepsia and atony of the stomach, or, if the unpleasant sensations are most pronounced after eating hard or heavy food such as black bread, potatoes, beef or pork, of gastritis.

A certain number of patients, when questioned about the nature of their pain, report as follows: The pains are burning, boring or cramp-like in character, with a feeling of contraction in the pit of the stomach. They commence either in the epigastrium, sometimes a little to one or the other side of the median line, but generally exactly in the median line, or they commence in the back. They may, however, start at the umbilicus, the lower end of the sternum, in the middle of the abdomen or in the right iliac region. From these starting points the pain may radiate in all directions—upward as far as the sternum, the shoulders and the intrascapular spaces, laterally to the arms and sides of the chest, and downward to the symphysis pubis. The intensity of the attacks may vary greatly, also their causes and the manner of their commencement, duration and termination. There are likewise great variations in the means used to successfully stop these attacks, be they home remedies or those prescribed by a physician. Lastly we find differences in the accompanying symptoms and in the relation of the attacks to the taking of food and to defecation.

We shall now see how it is possible by means of the above-mentioned points to determine in almost all cases the exact cause and location of the "stomach-ache" or gastralgia, without the absolute necessity of a physical examination or the use of the stomach-tube.

It is to-day accepted as practically certain, that the group of symptoms called "gastralgia" is caused by disease of the sympathetic plexus. Buch (*Archiv für Verdauungskrankheiten*, Bd. VII, Seite 535) has recently discussed these relations very clearly and thoroughly. He says that under normal conditions the sympathetic plexus is non-sensitive to pressure, but under pathological conditions only a slight irritation is needed to produce disagreeable sensations and ultimately the most severe gastralgia. At the same time the wave length of the sensitive nerves of the sympathetic plexus in regard to appreciating pain, is decidedly shortened. Buch, therefore, makes the logical suggestion, that we call this group of symptoms "epigastralgia," in order thereby to emphasize the fact that the pain is felt in the epigastrium, without necessarily having its origin there. I should like to follow Buch's example, and henceforth speak only of epigastralgia.

In proceeding to the special consideration of so-called gastralgia, we notice that attacks of pain or painful contractions in the epigastrium are observed in the most widely separated affections, and without much discrimination are by the laity called "stomach-ache." Just here it may be of interest to enumerate all the possibilities, and then consider them individually in point of differential diagnosis and treatment. We have to consider:

1. *Heart.* Angina pectoris.
2. *Intercostal Spaces.* Neuralgia, herpes zoster.
3. *Stomach.* Spasm of cardiac orifice, ulcer with spasm of pylorus, stenosis of pylorus, gastric spasm, nervous gastralgia.
4. *Duodenum.* Ulcus duodenale.
5. *Liver.* Biliary colic, cholangeitis.
6. *Pancreas.* Stones, hemorrhage.
7. *Intestines.* Colica mucosa, colica flatulenta, obstipatio spastica. Lead colic. Ileus. Herniæ. Intestinal stones. Enteralgia (in hysteria and syphilis). Acute enteritis and perityphlitis. Embolus of the arteria mesenterica. Tapeworms. Foreign bodies.
8. *Uterus, Kidneys, Ureter, Bladder.* Formation of stones. Colics.
9. *Peritoneum.* Peritonitis.
10. *Spinal Cord.* Tabes dorsalis.

In all these affections the average patient will complain of "stomach-ache" or "cramps." In every case we must discover the cause of the gastralgia, that we may thereby prepare the way for rational treatment. In passing, I would call attention to the fact that in general practice the following three conditions are frequently mistaken for one another—spasm of pylorus after ulcer, cholelithiasis and intestinal colic.

1. *Angina Pectoris.*—Here the attacks of colic are entirely independent of eating. They begin more in the region of the heart and radiate thence to the epigastrium, the shoulders, the back and the arms, especially the left arm. The attacks occur periodically, each lasting from a few minutes to quarter of an hour, and they often recur at a particular hour of the day. The diagnosis is easy, especially when the possibility of an attack is borne in mind. Elderly patients with pronounced arteriosclerosis, smokers, and syphilitics are prone to this trouble. It is unnecessary here to discuss the pathology and therapy of angina pectoris.

2. *Intercostal Neuralgia*, after "taking cold" and before the eruptive period of herpes zoster. Here, too, the patient complains of "stomach-ache," which radiates sometimes only to the left and sometimes to both sides, encircling the lower

end of the thorax, and reaching even to the back. In these cases the pain may be very severe. It comes on in jerks like supra-orbital neuralgia, and is increased and even started by pressure on the intercostal nerves. With a little care the diagnosis is easy.

3. *Stomach.*—As spasm of the pylorus accompanying ulcer is by far the most frequent cause of gastralgia, I shall consider it more carefully. In this affection the attack of pain always stands in intimate relation to the act of digestion. After light fluid food, such as soups, tea and milk it is usually absent. In a given case it recurs always at the same interval after eating, in some cases this interval is one-half an hour to one hour, in others one and one-half to three hours, in still others as soon as the stomach is empty, *i.e.,* four to five hours after the principal meal of the day, namely from six to seven P.M. and between midnight and 3 A.M. In the large majority of cases we find the secretion of hydrochloric acid above normal. Some authors claim that this alone is sufficient to produce spasm of the pylorus, but that this is not the case and that we must seek another reason, is evident from the fact that in numerous cases of nervous superacidity and gastritis hyperacida, after abuse of alcohol and tobacco, pressure symptoms are present after eating, but not spasm. This other reason can only be an ulcer, erosion, or fissure of the pylorus itself, or in the pars pylorica of the duodenum. Ulcers situated in other parts of the stomach run their course either entirely without symptoms, until hemoptysis takes place, or cause at most a burning, gnawing or boring pain, but never a spasmodic one.

I am well aware of the fact that many authors regard these pains in the epigastrium occurring regularly two to three hours after the principal meals, cramp-like and radiating in all directions, as essentially an expression of hyperchlorhydria, which may lead to an ulcer. I am, however, of the opinion that the ulcer is always primary and the hyperchlorhydria secondary, as a result of congestion and stagnation in the stomach.

By no means every ulcer is accompanied by hyperchlorhydria: there are plenty of cases with regularly recurring gastralgia after meals without hypochlorhydria, which recover promptly under treatment for ulcer.

A characteristic point in this sort of gastralgia is its stopping after the use of such antacids as bicarbonate of soda and magnesia usta, as also after warm drinks or a bit of bread. The explanation of this is not difficult. The superfluous free hydrochloric acid is diluted or combined and its corrosive action on ulcer, erosion, or fissure of the pylorus is counteracted. Thus the pain disappears, only to return again when a fresh unneutralized amount of HCl is secreted.

These cases of ulcer of the pylorus with hyperchlorhydria, easily recognized clinically by spasms of the stomach occurring at regular intervals after eating, form a transition to cases of stenosis of the pylorus. This latter condition may be a spastic one, or the result of scar tissue, both consequences of an ulcer, and sooner or later will lead to gastrectasia unless prevented by therapeutic measures.

Other forms of gastrectasia result from adhesions of the pylorus or pars pylorica with neighboring organs, or from compression from without. Thus it may be occasioned by gall-stones, tumors of the pancreas, peritoneal adhesions, etc. By these mechanical obstructions, the normal mobility of the pyloric end of the stomach is impaired and as this is the real motor force of the stomach, it follows that insufficiency, that is dilatation of the stomach, must result when the compensatory hypertrophy of muscle, in the course of time, has reached the limit of its capability to resist. In all cases of gastrectasia, the group of symptoms resulting in gastralgia appears when the stomach endeavors to force its contents through the narrowed passage into the gut. In the form of ectasis due to pyloric spasm, the stomach cramp occurs usually twice in the twenty-four hours, namely late in the afternoon and at night; in the other forms the cramp comes irregularly, when the overful stomach tries to empty itself of its contents, and owing to the narrow pyloric orifice does so into the esophagus.

The treatment of all these forms of gastralgia is that of the underlying malady, that is as if there were an uncomplicated ulcer present. If at all possible, make use of Leube's rest-and-gruel cure, and finally send the patient to Carlsbad, which is the sovereign cure for this form of ulcer when combined with hyperchlorhydria and spasms of the pylorus. We can also make use of the Mühlbrunnen at home, using two cups in the morning and one in the afternoon.

Of medicines I commonly use extract of belladonna, which limits the secretions, combined with bismuth, magnesia or sodium bicarbonate.

In recent cases of ulcus chloroticum I use, according to Boas, a solution of silver nitrate 1 to 400 giving a tablespoonful in a wineglassful of distilled water three times a day, quarter of an hour before meals, and confining the diet to soups and purées. In very old cases of ulcus chloroticum, and in all cases of ulcers especially in men, the result of chronic pressure on the epigastrium, I give, according to Fleiner, 10 grains bismuth subnitrate suspended in a glassful of lukewarm water on an empty stomach one hour before breakfast.

As an after-cure, I let my patient drink every morning, warm vichy, using later an emulsion of sweet almonds. I have also used to advantage in such cases Bellocq and Bergmann's chewing gum in tablet form and temporarily $^1/_{120}$ grain atropine tablets. In stubborn cases I have had good results from the use of oil, of which I have written elsewhere. In such cases I give a wineglassful of warm olive oil in the morning on an empty stomach, and repeat it at night if necessary. It can be administered either by mouth or by stomach-tube.

These methods of treating gastralgia due to

spasm of the pylorus have always worked well in my hands, except in cases of stenosis of the pylorus due to cicatrices or malignant growths. In such cases surgical interference is necessary, when lavage has failed.

Purely nervous cardialgia is very rare, as I wish, contrary to accepted views, especially to emphasize, and as is apparent from our discussion. It is only to be taken into consideration, after excluding gall-stones and intestinal colic, when it appears sporadically in nervously inclined patients after a psychic trauma. Usually it is accompanied by a dilatation of the stomach, because of the coexisting cardiospasm, which prevents the escape of gases. The attack ends with eructation. The treatment consists in hot compresses, hot valerian or peppermint tea and tincture of belladonna.

We may add to the affections simulating gastralgia, the symptoms of painful empty stomach, discovered by Boas. These painful pyloric contractions occur in nervous people whenever the stomach becomes empty, without producing any change in its chemistry. The pain is relieved by frequent small meals.

We find these painful contractions also occurring in gastritis atrophicans when the stomach becomes empty especially about 3 A.M.

In these cases the cause is a compensating hypertrophy of the pyloric muscles, the result of the effort necessary in constantly forcing coarse unchymified food into the duodenum, an effort greater than that required where the food is thoroughly chymified.

4. *Duodenum.*—Symptoms of gastralgia appear in cases of ulcer and stenosis of the duodenum exactly as in pyloric ulcer. As the treatment is the same in both sets of cases, a differential diagnosis is of little practical importance. We think of an ulcer or stenosis of the duodenum only, when during the course of an illness resembling ulcer of the stomach we notice icterus, or find bile constantly in the stomach contents.

5. *Liver.*—Laymen almost always mistake gall-stone colic for stomach-ache, and even physicians frequently do the same.

In such cases we must notice especially that the cramp occurs only sporadically, or periodically, and that after intervals of quiet of months or years, attacks may occur singly or in rapid succession. Rise of temperature and icterus accompanying such attacks are a pretty sure sign of biliary colic.

Inflammation of the gall-ducts without the passage of a stone is enough to produce colic. It happens frequently that gall-stones which have for years lain peacefully and quietly in the gall-bladder, are set in motion and produce colic through some sudden emotion such as anger. There is much truth in the old superstition that violent anger produces colic and jaundice. This is not the place to speak of the treatment of attacks of biliary colic.

As a further point in the differential diagnosis between biliary colic and ulcer with spasm of the pylorus, it should be mentioned that pain on pressure is elicited in the former in the region of the gall-bladder, and on the right side posteriorly, while with the latter it is found in the median line in front and posteriorly to the left of the spine. Furthermore biliary colic is entirely independent of meal times, while spasm of pylorus stands in direct relation to eating.

These differential points should be sufficient to make the diagnosis easy.

6. *Pancreas.*—Attacks of gastralgia due to stones or hemorrhage in the pancreas are only then to be diagnosticated when diabetes or fatty stools are present, otherwise we cannot differentiate between them and biliary colic. The possibility of this condition should however be kept in mind.

7. *Intestines.*—I need only briefly mention the affections which a layman might confound with stomach-ache such as perityphlitis, acute colic with diarrhea, and hernia. In addition to these is embolus of the intestinal arteries, which may produce severe gastralgia, and which is only diagnosed by the subsequent severe intestinal hemorrhages.

Lead colic also produces severe gastralgia, but this condition should not lead to mistakes unless it is entirely overlooked.

Of more importance are the colics accompanying obstipatio spastica, whether produced by gas or mucus, and respectively called colica mucosa and colica flatulenta. How often are these forms of colic confused with genuine gastralgia! Only the condition of the patient's stools saves us from errors. If these colicky attacks occur generally just before diarrheal movements, the diagnosis is easy. We must always inquire carefully about this, as patients are careless in taking notice themselves.

With colica flatulenta, pain ceases or is much lessened after passing wind, and also, as in cases of spasm of the pylorus due to hypersecretion, after warm drinks or hot compresses. Warmth internal or external resolves the spasms of the colon. Very rarely does this form of colic occur directly after meals, and then only in very sensitive patients. Usually such wind colic is entirely independent of eating, and thus easily diagnosed.

We have already noted the treatment of this wind colic. In addition we should forbid the use of cold drinks and food causing flatulence, such as fresh bread, cheese, cabbage, pears, cucumbers, and hard boiled eggs, and give carminatives and, as a matter of routine, belladonna.

Colica mucosa offers similar conditions and is an exacerbation of chronic colitis caused by constipation and abuse of cathartics extending over many years.

During attacks of colic, which are often called "stomach-ache," pieces of mucous membrane are passed, and these readily indicate the diagnosis. When these pieces of mucous membrane are absent, we may suspect a colica mucosa from the passage of irregular lumps of feces of small cali-

ber and surrounded by mucus, and, furthermore, from band-like contractions of the colon.

In treating these cases we have two problems, first to relieve the acute attack, which we do as in cases of wind colic, adding an enema of oil, if needed, and second, to control the chronic spastic obstipation. The diet should consist of food containing a moderate amount of cellulose and plenty of fruit juice and organic acids, such as buttermilk and kefir, and to this should be added several weeks' treatment by means of oil enemata and packs.

With a little thought colica mucosa is like the other colics easily differentiated from gastralgia.

The remaining intestinal affections are so rare that we need but mention some of them, such as acute ileus, strangulated hernia, especially in the epigastrium, and colic resulting from worms and foreign bodies, like pears and fruit seeds. It would carry us too far to discuss each one.

Of these the epigastric herniæ deserve some notice, as the pain they cause may resemble that of ulcer or gall-stone colic. We may avoid mistakes by noting first that they are usually visible and palpable in the linea alba, and second, that they are directly dependent upon relaxation of the recti muscles, and appear especially on bending over, lifting, coughing, sneezing and forcing at stool.

8. *Urogenital System.*—Owing to the reflex vomiting occurring so often in pain due to stones of the kidney, ureter and bladder and to dysmenorrhea, these conditions may be mistaken for gastralgia. A little attention to the source of such pain will exclude all but the right cause, and examination of the urogenital system will clear up the diagnosis.

9. *Peritoneum.*—For the sake of completeness I will merely mention the colic produced by inflammation of the peritoneum and accompanied by vomiting.

10. In conclusion, as is well known, we may have gastralgia accompany tabes dorsalis. Merely bearing in mind this possibility will often suggest the diagnosis.

The "crises gastriques et enteriques" occur paroxysmally every few months or years. Every case of periodical cramp of the stomach accompanied by vomiting makes us suspect tabes, and frequently these crises are the first symptom, followed only after two or three years by the complete picture. Usually, however, the complete picture is present at once.

Treatment is naturally most unsatisfactory and I confine myself to gastric lavage and giving morphine or oxalate of cerium.

This concludes my discussion of differential diagnosis. I do not add any histories, as every physician has had plenty of his own, though perhaps he has not always interpreted them rightly. I wish to emphasize once more the fact that there are three principal conditions to be considered in cases of gastralgia, or stomach cramp, namely, *spasm of the pylorus, biliary colic* and true *colic of the transverse colon.*

I trust I have proved it possible, even without the aid of the stomach tube, so to differentiate the various affections which can produce symptoms of gastralgia, that each may be treated clinically, in a rational manner.

The means of so doing, I repeat, are careful consideration of the history of each case, the time of occurrence of cardialgia, its duration, its relation to eating and defecation, its suppression by means of warmth, antacid remedies, etc., and the relation to it of secondary symptoms such as icterus, hematemesis, melena, and pains in certain regions.

---

## RESECTION OF THE LEFT PELVIS FOR OSTEOSARCOMA.

BY M. STAMM, M.D.,
OF FREMONT, OHIO.

In the Medical News of March 14, 1903, I see that Prof. Keen, of Philadelphia, performed an operation for the removal of an osteosarcoma of the pelvis, where it was mentioned that a similar attempt had never been made before in this country. The following case was operated on May 15, 1901, and would, therefore, precede Dr. Keen's case nearly two years.

F. S., of Monroeville, O., age twenty-five years, barkeeper, was treated for rheumatism for about one year. About four months ago he began to notice a swelling above his left hip-joint at the upper portion of the sacro-iliac joint. I saw him about the beginning of May, the tumor appeared to be semi-elastic, veins enlarged, the skin showed

Fig. 1.

Osteosarcoma of Pelvis.

marks of overdistention. The tumor was about the size of a child's head, reaching from the sacrum to the hip-joint. After patient had seen some other surgeons and heard their gloomy prognosis, and after I had explained the great danger of such a formidable operation he insisted upon prompt interference and was willing to take any risk. The successful issue in one case operated upon by Prof. Kocher, in Bern, and one by Prof. Roux, in Lausanne, Switzerland, gave me some slight hope of a similar result, especially as patient seemed to be in fair health. The operation was undertaken on May 15, 1901, in the presence of Drs. McCormick and Phillips, of Fremont, Dr. Burt, of Norwalk, Drs. Kreider and Pritchard, of Monroeville, Dr. De la Barre, of Port Clinton, Dr. Heller, of Oak Harbor, and Durbin, of Woodville, O.

The incision was made from the sacro-iliac synchondrosis along the rim of the pelvis, down to the inferior iliac spine and to the hip-joint. The abdominal muscles were separated from the rim of the pelvis, the iliacus muscle was stripped off the ileum, the tensor vagina, sartorius and gluteus medius were also divided, Poupart's ligament separated and muscles pushed aside. Owing to the size of the tumor it was difficult to open the hip-joint and to remove the head of the femur with Gigli's saw. The joint proved to be healthy and could have been avoided if the tumor had not encroached upon its neighboring territory. The pelvis was divided about one inch in front of the hip-joint with saw and chisel through the ischium and horizontal ramus of the pubis. The chisel was used for the sacro-iliac synchondrosis and it showed that the tumor originated from its upper portion and was attached along the outside of the ileum to the periosteum, and its anterior pole worked itself between the gluteus medius and gluteus minimus. Hemorrhage was not very profuse, but the shock very great and was very much increased by the chiseling. Saline injections, subcutaneous and intravenous, as well as strychnine and camphorated oil did not make any impression and patient died about five hours after operation. From this case I have gained the impression that patients do not bear chiseling well and a saw driven by some motor would perhaps be the best way to separate the bones. I think that if the operation had been done in two sittings or if the resection of the hip-joint had been evaded the result might have been different.

Site of Operation.

## THE PALLIATIVE TREATMENT OF FIBROID TUMORS OF THE UTERUS.*

BY AUGUSTIN H. GOELET, M.D.,
OF NEW YORK;
PROFESSOR OF GYNECOLOGY IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; GYNECOLOGICAL SURGEON TO THE METROPOLITAN HOSPITAL FOR WOMEN AND CHILDREN; ETC.

The palliative measures in fibroid tumors of the uterus are to be classed as follows, viz.: 1. Oophorectomy. 2. Cutting off of the blood supply by obliteration of the uterine arteries. 3. Dilatation of the cervix with curettage of the endometrium. 4. Electricity. 5. Medication; including the administration of animal extracts.

In the light of later developments of modern surgery palliative treatment of fibroid tumors of the uterus is to be limited to the following conditions, viz.: (1) When some constitutional or local condition forbids removal of the growth; (2) when the patient declines operation; (3) when the growth is small and is not producing

* Read by request in the Section on Gynecology of the New York Academy of Medicine.

inconvenience, except when the abdomen is opened for some other purpose, in which case these growths should always be removed from the uterine wall when found whenever it is feasible; (4) in young women, when the possibility of removing the growth and leaving the uterus and ovaries behind cannot be definitely determined beforehand.

Oophorectomy as a palliative measure in these cases I have done only a few times and have limited it to women approaching the menopause who had small tumors that were producing intolerable symptoms, such as pain and hemorrhage, that resisted other measures including electricity and curettage. So far as I am now able to recall the results were fairly satisfactory and in two cases where the growths were small they disappeared.

In the class of tumors where this operation would be of benefit, viz., in small sessile or interstitial growths, it should be done as a matter of necessity rather than of choice when their removal is not practicable or the increased risk is not justifiable in individual cases.

Cystic and subperitoneal growths are not benefited by removal of the ovaries. The ovarian arteries should be obliterated when the ovaries are removed for this purpose.

The mortality of this operation is said by Roger Williams to be 10 per cent., but I fail to see how that is possible. The same author states also that it is of more benefit in young women with myomata of small size. I consider it positively unjustifiable in young women.

Cutting off the blood supply by obliteration of the uterine arteries has been productive of good when the growth is interstitial and it is small and is situated below the fundus. When done with the proper limitation it has in my hands produced marked reduction in the size of the tumor and in some instances complete disappearance; and there is always notable arrest of bleeding from the endometrium. To be effective, it is essential that the arteries on both sides should be permanently obliterated by applying two ligatures and dividing the vessels between them.

Dilatation of the cervix and curettage of the endometrium accomplishes a double purpose, viz.: First, and chiefly, arrest of hemorrhage, and, second, stimulation of the muscular fibers of the uterine wall to contraction whereby extrusion of the growth either towards the peritoneal side or into the cavity of the uterus is favored. Great care is necessary both in effecting dilatation and in using the curette in these cases lest rupture or laceration may result from the former or perforation through a very thin uterine wall may be caused by the latter. Gradual dilatation by means of sponge or laminaria tents is safer than rapid dilatation with the steel dilator and if the tent is protected by a rubber cover as I have directed elsewhere* the risk of sepsis is completely obviated.

Curettage should be done only with the dull instrument or one with copper edge and it should be as large as the canal will comfortably accommodate to lessen the chance of perforation of the uterine wall when it is thin. Following curettage the cavity should be freely irrigated with hot water or salt solution to remove loosened membrane and clots, and afterward with a solution of iodin in hot water. By using the compound tincture of iodine a perfectly clear solution is obtained in which there is no precipitate of iodine. The strength of this solution may be from half an ounce to an ounce to the pint. Iodine in its full strength should not be applied to the endometrium.

Electricity has been much abused and much misused in these cases. It is of undoubted benefit when used properly in appropriate conditions. (1) It will nearly always relieve the pain to a very considerable extent, though sometimes owing to the situation of the growth it does not afford relief. (2) It will arrest the hemorrhage when it is possible to reach all parts of the cavity of the uterus for contact with the electrode. In some instances, however, it is necessary to precede the application by dilatation and curettage to bring about a more prompt and decided result. (3) It will relieve in a measure congestion of the uterus and diminish the blood supply to the growth. (4) It will in suitable cases bring about very considerable reduction in the size of the growth. (5) When the growth is a true myoma of moderate size it will sometimes eventually disappear under prolonged applications of electricity to the endometrium. (6) It will sometimes facilitate extrusion of the tumor and thus favor its enucleation. (7) It will sometimes cause breaking down of the intervening wall between the growth and cavity of the uterus and expulsion of the tumor from the uterus. When such result is produced great care is necessary to obviate sepsis.

Electricity is then useful in many cases for relieving the symptoms produced by fibroid tumors of the uterus, but in some of these conditions (notably in subperitoneal and submucous growths) it is powerless to accomplish any good and should not be used. If it is to be applied with the intention to reduce the size of the tumor its use should be limited to small interstitial growths that have not developed so as to rise above the umbilicus. In growths of larger size than this even if they are interstitial, it is of little or no material benefit though sometimes it does relieve the pain to a very considerable extent. I am obliged to admit that the results obtained by electricity in these cases is not always permanent. I believe that it is only possible to obtain decided results by making the applications to or through the endometrium and thus more directly to the growth proper. The galvanic is the most useful current and the only one that will effect decided reduction in the size of these tumors. The faradic current is useful sometimes for relieving pain, as is also the static induced current.

Medication will sometimes prove a valuable

* "The Technic of Surgical Gynecology," p. 57, by the Author. International Journal of Surgery Co., New York, Publishers.

auxiliary to the palliative treatment of fibroids of the uterus. Ergot has been found useful in some instances. It acts, I think, by producing continuous contraction of the muscular wall surrounding the growth which causes diminution of the blood supply and favors extrusion of the mass.

The iodide and bromide of potassium are useful sedatives and afford much relief in some cases.

Arsenauro (bromide of gold and arsenic) exerts a marked effect in hemorrhagic cases. When given in full doses and continued persistently the bleeding is very materially lessened. It is also useful for counteracting the anemia caused by prolonged bleeding.

Extract of the thyroid and mammary glands are said to exert a decided action in these cases but my experience with them has been negative.

2030 Broadway, New York.

## MEDICAL PROGRESS.

### MEDICINE.

**Hematogenous Miliary Tuberculosis of the Lungs.**—It has generally been believed that miliary tuberculosis of a hematogenous origin, was due to the deposit of the tubercle bacilli in the smaller capillaries of the lung, from which the process extended. Ribbert lately suggested, however, that the bacilli found their way from the pulmonary capillaries into the lymph channels and becoming collected in the lymphatic nodules, brought on pathological changes in the neighborhood of the latter. Experimental proof of this view has now been furnished by the researches of K. Sawada (Arch. f. klin. Med., Vol. 76, No. 4), who used very virulent cultures of human and bovine tubercle bacilli for injection in rabbits. Microscopical sections of the lungs showed that in each case the resulting miliary tuberculosis had its origin in the lymph nodules. The bacilli circulating in the blood, unless they are clumped in large masses, can not be caught in the comparatively large alveolar capillaries, and only become imprisoned when they find their way into the much narrower capillaries of the lymphatic nodules. A marked difference was found in the pictures presented by the lungs of young and adult rabbits, the signs of pulmonary disease appearing somewhat earlier in the adult than in the younger animals. This point the author believes, may have some value in explaining why pulmonary tuberculosis is less frequent in young children than other forms of tubercular lesions. In man the lymphatic nodules are not fully developed until the fifth to the seventh year. If the pulmonary involvement dominates the clinical picture of a case in the first five or six years of life, it may be assumed, judging from the author's experiments, that the infection resulted from the penetration of numerous and very virulent bacilli into the pulmonary circulation.

**Influence of Dwellings on Tuberculous Disease.**—Marburg is a small city in Germany of about 18,000 inhabitants and serves as a good example of conditions existing in other cities of a similar size. A study of these conditions as regards their influence on tuberculous disease has been made by Romberg and Haedicke (Arch. f. klin. Med., Vol. 76, No. 4). The proportion of the population suffering from pulmonary tuberculosis is 1.1 per cent., four-fifths of the deaths from the disease being found in the poorest quarter. Among the latter class, the number of phthisis cases was 4.7 per cent., whereas among the better situated class, the percentage was only 0.2 per cent. The distribution of the disease seemed also to be restricted to certain dwellings, 59.2 per cent. of the cases in the poorer quarters occurring in 33 per cent. of the houses of the lower class. It was found, however, that locality, mode of construction and the number of tenants had no apparent bearing on the number of cases of tuberculosis, nor did the latter appear to be influenced by the filth in the apartments. Direct infection seems to be the main factor in the spread of the disease. A single infection may not be followed by any pathological results, but the principal danger appears to lie in the continued association and contact with a phthisical subject amid filthy surroundings and who is careless regarding the disposition of his expectorations. This is the main reason why the disease is so often localized in particular dwellings and the fight against the disease must be conducted in the quarters of the poor, especial attention being paid to continued re-infection.

**Observations on the Blood in a Case of Extirpation of the Spleen.**—Some interesting observations have lately been made on the blood of a patient in whom the spleen was removed on account of rupture and laceration sustained by an accident, by R. Staehelin (Archiv. f. klin. Med., Vol. 76, No. 4). He compares his case with the 21 others which have been reported in the literature, and finds a number of points of difference, especially in the relation of the spleen to the blood constituents. In the larger number of cases there was reported a swelling of the lymphatic glands and this symptom was particularly marked in the author's case. In the cases where no enlargement was reported, it is not unlikely that it may have been present, but situated otherwise than in the peripheral glands. Another point which the author notes was the liability to infection which the patient presented, after the spleen had been removed. For some months the patient also experienced severe pains and weakness in the extremities, both femur and tibia being particularly sensitive to pressure. This may be ascribed to disturbances in the marrow of the long bones, for it is well known that the latter and also the spleen are the depositories of the broken down red cells. The blood examinations showed that at first the multinuclear neutrophiles were very much diminished, then increased perceptibly and finally sank to the normal numbers, this phenomenon corresponding, however, with the development and subsequent disappearance of an infectious process in the operative wound already noted. The lymphocytes, however, showed a marked increase which coincided with the swelling of the lymphglands and probably depended on a greater activity of the lymphatic apparatus during the presence of an infection. As far as the red cells are concerned, the spleen seems to have no effect whatever on their relative numbers. Its only influence is apparently on the lymphocytes. This increase may be explained by assuming that the spleen does not produce lymphocytes, but subserves some other function, which may be taken up by the lymphatic glands. This may be a production of or a change in some chemical body, or the absorption of the products of disintegrated blood. In this way the increase in the lymphocytes after splenectomy may be accounted for by the increased function of the lymphatic glands, the spleen not taking any part in the process. It seems, therefore, that the spleen has no function as a blood producing organ.

**Primary Cancer of the Pancreas.**—The principal interest of the case lies in the fact that notwithstanding the affection of the pancreas there was no glycosuria. Manouloff (Pract. Vratch., No. 23, 1903) diagnosed the case with comparative ease, as it presented all the symptoms of a malignant growth. He explains the ab-

sence of glycosuria by the complete destruction of the hepatic tissue. The patient was admitted to the hospital with general weakness and abdominal pain. The skin and the visible mucous membranes were markedly icteric. The abdomen large (34½ inches) and excessively tender; face and lower extremities edematous; marked arteriosclerosis (patient fifty years of age). The liver greatly enlarged, hard and very tender to touch. Annoying pruritus all over. Spleen enlarged. Nausea and constant pain in the region of the stomach; no vomiting. Urine contained some albumin, abundant biliary pigments, but no sugar. The feces colorless, with a strong odor, and a great quantity of fat corpuscles and undigested muscular fiber. Patient eats and drinks a great deal. After drawing off the ascites it became possible to detect in the linea alba under the left lobe of the liver a hard undulated swelling the size of a fist and hardly movable. The patient succumbed after nine months of suffering to extreme asthenia. Microscopically the pancreas was converted into a tumor with a strongly developed connective tissue stroma, containing in its fibers groups of parenchymatous elements of the new formation; these elements resembled polymorphous cylindrical epithelia surrounding cavities of various sizes, the whole looking much like a glandular swelling. Nothing remained of the pancreas. The liver was also greatly changed. It is of interest to note that while the head of the pancreas was attacked by the malignant growth, its body and tail underwent cystic degeneration, some of the cysts having reached a very large size. This combination of pathological processes in the pancreas has been observed quite frequently. Besides the liver the kidneys were also found to be the seat of a chronic interstitial nephritis, while the spleen showed marked hyperplasia due evidently to cirrhotic changes in the liver.

## SURGERY.

**Resection of the Clavicle.**—Three cases of partial and total resection of the clavicle are reported by P. Mauclaire (Trib. Méd., June 27, 1903), apropos of which he discusses the indications, technics and functional results of the operation. The indications for such a measure he holds to be comparatively rare; a partial resection having been performed in one of his cases for tuberculous osteitis and a second for comminuted fracture; a primary lymphosarcoma of the clavicle rendering extirpation of the bone necessary in a third. As to the technics of total extirpation, he describes two methods; one of which consists in disarticulation of the acromio-clavicular joint and severance of the attachments of the bone from without inward; in the second method the bone is resected at its mid point and the two fragments extirpated successively. The mortality of the operation is said to be practically nil; but in the extensive resections essential to the surgical treatment of neoplasms, the author emphasizes the necessity for the greatest care in approaching the internal extremity of the bone, as at this point entrance of air into a vein has been known to occur. Upon the integrity of the muscles inserted in the scapula, depends functional reestablishment after total extirpation; the former developing an active resistance which takes the place of the normal clavicular points of support; so that practically the normal range of movements is possible, as in partial or total congenital absence of the clavicle. A flattening of the shoulder is seen after such operations.

**Painful Affections of the Feet Among Trained Nurses.**—The liability of trained nurses to develop some static trouble with their feet during their term of hospital service is well known and is of considerable practical importance. R. W. Lovett (Jour. Am. Med. Ass'n, July 4, 1903) records the observations made during a period of eight years upon some 800 nurses in hospitals, all of which were examined on admission and suitable shoes or other treatment prescribed as demanded. The results obtained are very interesting. It was not possible to tell with certainty by examination whether or not the feet of an individual are likely to give trouble. The only reliable information was derived in these cases from imprints of the foot seen through glass, supported on a table over an aperture with a mirror underneath. A foot with a well distributed pressure area seems rather less likely to give trouble, than one resting on two islands. Other factors seem to be of little consequence, a flat foot may be perfectly serviceable as may also a severely pronated one, while an apparently well-balanced foot may become painful. The factors in causing the trouble among the nurses were to be sought rather in the general conditions than in any special conformation of the foot, following in many cases, illness and other conditions causing muscular debility. It occurred in most cases in from two to three months after admission and in the early spring, after the nurses had been indoors more and least often in the fall. The trouble was caused by a rolling in of the foot and a shifting inward of its weight bearing areas and not in any case observed by a breaking down or a lowering of the arch. The author believes that the use of a proper boot has done much to relieve the condition. The treatment consisted of the use of felt pads worn in the shoes during the day and the immersion of the feet at night in hot water followed by a cold shower and the application of a flannel bandage. In severer cases, a metal plate is worn in the shoe or a felt pad with adhesive straps which hold the foot in an inverted position. If no relief the patient is enjoined to keep off her feet and then begin to take long walks out of doors.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Regarding Hemolysis in Experimental Infections.**—To the numerous contributions on the subject of bacterial hemolysins which have lately appeared, is added another by O. v. Wunschheim (Münch. Med. Woch., June 30, 1903). His researches were concerned with the question whether during the course of an infectious disease, the pathogenic microorganisms could cause the formation of hemolytic substances in the animal body and under what conditions. A large number of the lower animals were inoculated with cultures of various pathogenic bacteria, mostly of anthrax. The observations were made on centrifuged specimens, the color of the supernatant serum being noted in comparison with the normal. This seemed much simpler than taking a numerical count of the destroyed red cells. In the anthrax infections a sudden and intense hemoglobinemia was observed and the author proposes calling the purplish serum, "serum purpureum," to distinguish it from the minor grades of hemoglobinemia which were also found in other experiments. The author believes that similar processes also take place in the bodies of human beings, but are not recognized. A mild degree of hemoglobinemia may take place during the course of an infectious disease, without the production of a hemoglobinuria, and not be detected for lack of practical means of testing for it. Experiments are now in progress, from observations made in typhoid and influenza, to determine under what conditions, hemoglobinemia in infectious diseases is a constant factor, and whether the methods practised by the author can be made of clinical and prognostic value.

**Bactericidal Action of the Radium Rays.**—A preliminary communication in this subject is published by

R. PFEIFFER AND E. FRIEDBERGER (Berl. klin. Woch., July 13, 1903). A small quantity of radium bromid enclosed in a suitable rubber capsule, was placed some 2 or 3 inches away from a gelatin culture plate containing a large number of typhoid and cholera colonies. The experiments were conducted in a darkened room. The results even after 24 hours' exposure were negative. The distance was then decreased to ⅓ of an inch, and in 48 hours' time an area of about ⅔ of an inch in diameter was observed, in which no further growth took place. To determine whether this may not have been due to some change produced in the culture medium by the action of the rays, the sterile area was again inoculated with a fresh typhoid culture. An abundant growth was seen in 20 hours. Similar results were also obtained with cultures of cholera and anthrax. Whether there is an absolute death of the organisms or only prolonged interference with their development is still an undecided matter, but the authors believe there is a favorable field afforded in the treatment, especially of infectious processes of the skin, such as lupus and others.

**Pathology of Latent Malarial Infection.**—By the latent is meant a malaria which is not manifested by any symptoms and in which an examination of the blood does not necessarily show the presence of the malarial parasites. Pathological changes in the organs of these cases are only found at autopsy after death from some other disease. C. F. CRAIG (Am. Med., July 25, 1903) reports a series of seven cases of this character, three tertian and four æstivo-autumnal. In all these latent infections the pathological lesions were chiefly confined to the spleen and the liver, whereas in the acute infections it is known that almost every organ of the body is involved. The changes in the spleen consisted chiefly in an engorgement of the splenic sinuses with red cells and leucocytes, the presence of infected red cells and of phagocytes and of melaniferous leucocytes, an increase in the cells of the splenic pulp with more or less degeneration and karyokinesis and pigmentation of the organ confined to the edges of the Malpighian corpuscles and the splenic sinuses and trabeculæ. In the liver the changes consisted in slight pigmentation, more or less venous congestion, and the presence of melaniferous leucocytes. The changes in the æstivo-autumnal form differed but slightly and chiefly in the character of the parasites present. The chief point of value is that the parasites were found to undergo their entire normal human life cycle within the spleen, without being detected in the peripheral circulation or causing any evident symptoms. This also bears out the old theory that the spleen is the seat of the malarial infection. In any one of these cases, puncture of the spleen would have resulted in a diagnosis, but the author is of the opinion that this procedure is too dangerous even in experienced hands and not to be advised as a routine measure or in cases such as these where no malarial symptoms are present.

**A Cavernous Tumor of the Spinal Cord.**—An instance of this hitherto unreported condition is published by R. HADLICH (Virchow's Arch., Vol. 172, No. 3), and its relations to the newer theories regarding the origin of cavernous tumors discussed. The specimen was secured from a patient who had died two days after Cesarean section had been performed on account of a narrow pelvis. At no time had there been any symptoms referable to the tumor which was as large as a pea and occupied a position on the dorsal aspect of the lumbar section. A cross section showed marked disturbances in the relations of the various parts, and in the region of the posterior horns, were numerous cavities of larger and smaller size, which apparently originated in the neighborhood of the posterior nerve roots and extended towards the center and the anterior horns. Most of these canals were found to contain blood and were lined by a single layer of endothelium. The only analogous cases are those of a cavernous tumor of the liver, of which numerous cases have been reported and theories as to their origin proposed. The author is unable to relate his own case to any of these and comes to no definite conclusions as to its etiology.

**Staining Elastic Fibres.**—A new method by which it is possible to stain both elastic fibres and fat at the same time, is proposed by B. FISCHER (Virchow's Arch., Vol. 172, No. 3). Such a procedure is of especial value in the examination of areas of fatty degeneration in vessels, kidneys, lungs, etc. To 74 cc. of fuchselin there is added 26 cc. of distilled water and the mixture brought to a boil. An excess of scarlet R. or sudan III is added and the mass allowed to cool. The section does not come in contact with ordinary alcohol in any form, which would dissolve out some of the fat, but the differentiation is accomplished with a hot saturated solution of scarlet R. or sudan III, in 70 per cent. alcohol. The latter solution does not affect the fat. The sections are first placed in the fuchselin mixture for one hour and then for fifteen minutes in the hot alcoholic scarlet or sudan solution. They are then washed in water and mounted in glycerin. It is not advisable as a rule to combine with this any nuclear stain on account of the multiplicity of colors, but if desired, the sections may be placed in acetic acid-methyl green solution and then differentiated in acidulated water. If care is taken, the nuclei appear of a delicate pale green color.

**The Formation of Gall-stones.**—With the endeavor to throw some light on the formation of gall-stones, V. HARLEY and W. BARRATT (Jour. of Physiol., June 15, 1903) observed the effect of introducing cholesterin calculi or fragments of calculi into the gall-bladder of dogs, both in health and in various morbid states. A series of five experiments all gave results similar to the following experiment: Two cholesterin fragments were introduced into the gall-bladder; the dog was killed 265 days later and necropsy performed. Both gall-stone fragments had disappeared; the gall-bladder, cystic duct and bile were all healthy in aspect. All the animals had remained in good health except one, which lost weight. In a second series of experiments, besides the calculi, dry pus or pus containing the *Bacillus coli* was introduced. The dogs remained in apparently perfect health, nevertheless the autopsy revealed cholecystitis and no dissolution of gall-stones occurred. In two experiments where only gall-stones were introduced, the latter were found unaltered, but cholecystitis was present and bacilli were found in the contents of the gall-bladder. It would therefore appear that when the gall-bladder is healthy the gall-stones seemed to disappear; on the other hand where cholecystitis was present the gall-stones remained unchanged. In the second series of cases the following changes were met with: The columnar epithelium of the mucous membrane of the gall-bladder was in every case covered with an amorphous or finely reticulated deposit, which could not be well stained with a fibrin stain nor with any of the other stains employed. Sometimes this deposit contained micro-organisms. The epithelial cells themselves were swollen and presented in the middle and upper part of their cytoplasm a clear vacuolated aspect. Lying among the epithelial cells, wandering cells could also be seen in sparse numbers. The connective tissue of the mucous coat sometimes appeared wide-meshed as if edematous and the capillaries of the mucous membrane were sometimes congested.

## OBSTETRICS AND GYNECOLOGY.

**Maternal and Fetal Temperatures.**—The temperature of the child at birth is stated by most observers to be about the same as that of the mother, or a little higher. In 33 births S. G. CHAMPION (Brit. Jour. of Obstet., June, 1903) made examinations of both the fetal and maternal temperatures and came to the following conclusions: The temperature of the fetus in utero is higher than that of the mother. The exact amount of disparity it is impossible to determine, because during the process of expulsion of the child its temperature is already beginning to fall, the result of loss by heat radiation by the skin; immediately after birth the rectal temperature of the child still shows an average excess of 1.0° F. over that of the mother. The raised temperature never persists, but immediately and rapidly falls in the next fifteen to twenty minutes. The heat loss must have undoubtedly occurred by the skin and from the lungs. In no case was a bath administered to the child until after the observations were concluded.

**Injuries to the Child's Head During Delivery.**—In ordinary practice, depressions of the skull caused during parturition are not very common; as a rule, ROBERT JARDINE (Brit. Jour. of Obstet., June, 1903) found that they occurred in contracted pelves, and are caused by pressure of the promontory, but they may occur in normal pelves. Fracture may occur during delivery and yet there may be no depression evident at a casual examination. Besides injuries to the bones other serious injuries may arise, such as cortical or meningeal hemorrhage, traumatic keratitis, hemorrhage into the optic nerve, or anterior chamber of the eye. Subconjunctival hemorrhages are exceedingly common even in normal labors, but they are of no consequence. If cortical and meningeal hemorrhages do not cause death there is liability of permanent injury to the brain. Very little can be done in hemorrhages but to leave them to nature. If there is fracture, a trephine might be used, but in some cases where there is no fracture or depression it is difficult, and, at times, impossible, to locate the hemorrhage. In high forceps deliveries one blade of the instrument usually lies over or near one of the eyes, and occasionally the eye is more or less injured. In difficult deliveries the eye may be enucleated. Hemorrhage into the anterior chamber is occasionally seen. Retinal and hemorrhages into optic nerve may also occur. There may be a condition which Ernest W. Thomson calls "traumatic keratitis in the newborn." The author recalls one case of his own in which the child had been delivered with axis traction forceps and twenty-four hours later one cornea was more or less opaque.

**Uterine Pregnancy Following Operation for Extra-uterine Gestation.**—The fact that a woman who has recovered from an operation for extra-uterine pregnancy is liable to a similar accident is in the proportion of one to four, makes F. D. DONOGHUE (Am. Jour. of Obstet., July, 1903) report two cases of normal pregnancy following operation for extra-uterine gestation. One occurred after a vaginal operation, while the other had been preceded by an abdominal operation. The causes of extra-uterine gestation group themselves naturally into (1) cases in which the tube is ruptured or aborted, and (2) those cases diagnosed before rupture. The first group also divides into cases of pelvic or broad ligament hematocele, and free hemorrhage into the abdominal cavity. If one is going to be conservative in operating upon extra-uterine pregnancy, that is, leave in the tubes and ovaries, with a view to subsequent normal pregnancy, the author believes that the patient or the patient's relatives should be consulted as to their wishes in the matter, provided they have been previously warned of the probability of the occurrence of a second extra-uterine pregnancy. All such cases should be carefully watched after the operation. As with an increasing number of reported cases, normal pregnancy, it appears, is much more apt to occur than a repetition of an extra-uterine. Thus it would seem that one is justified in being conservative in operative procedure; but careful watch should be kept for the slightest deviation for a normal menstruation following the operation.

**Placenta Previa.**—Of all the complications that the obstetrician has to contend with there is none that is fraught with more danger or attended with greater anxiety than this condition, save, perhaps, eclampsia. If complications cause placenta previa to result in a high maternal mortality. JOHN F. MORAN (Am. Jour. of Obstet., July, 1903) finds that this is somewhere between 1 in 300 and 1 in 1,000. Placenta previa is seven times more frequent in multiparæ than in primiparæ. In 5,000 births at the Columbia Hospital, Washington, D. C., it has occurred 16 times or once in 312.5 births. Of these there was one maternal fatality and six infants were lost. The author has collected from literature 16 cases by 13 operators, where Cæsarean section has been performed for placenta previa. Five mothers died, or 31.5 per cent., and four infants were lost, or 25 per cent. Eleven children were delivered alive. Seven were done after the Sänger method; eight were of the Porro variety; one unknown. In lateral placenta previa there is rarely any difficulty, and labor usually terminates naturally. In the marginal, however, it becomes more dangerous and the central variety is always a matter of gravest concern. Hemorrhage and sepsis are the most important dangers in all cases of previa, and to these rupture of the uterus may be added as a third factor in accouchement forcé and more particularly where an attempt is made to deliver the child through an insufficiently dilated cervix. Regarding the absolute indications for Cæsarean section in placenta previa, statistics are not very encouraging, but usually it has been performed for repeated hemorrhages where and after other methods of intervention have failed. Whether these results will improve will depend upon a more thorough study of the cases during pregnancy, early recognition and prompt action while the patient is in good condition.

**Cervical Incisions in Labor.**—The use of this procedure is by no means a new obstetric finding, says R. W. HOLMES (Am. Jour. of Obstet., July, 1903), for a century or more, cutting operations upon unyielding cervices have been fully recognized. It is applicable and indicated after effacement of the cervix has taken place. In contributory indications their use is a moot question; the judgment of the operator must decide in individual cases. For this reason incisions are especially applicable in primiparæ, and often contra-indicated in multiparæ. Manual dilation previous to incisions does not secure the best conditions for the incision. Incisions are potentially dangerous; the dangers comprise infection, hemorrhage, and extensive lacerations beyond the vaginal vault. The use of incisions demands an obstetric armamentarium, assistants, and a definite experience in obstetric procedures. The details of the technic may be modified to suit the taste of the operator. The minimum number of incisions should be made to meet the exigencies of the case. Oblique incisions can be proven to be more advantageous as regards the after-effects than the usual quadrant cuts. In the absence of hemorrhage or accessory lacerations, it is a moot question whether or not the incisions should be sewed up. Immediate delivery should follow the incisions in every instance.

**The Bossi Dilator.**—The principle claimed for this instrument is that a constant elastic pressure upon the cervix will dilate it evenly and safely, even though great

force is employed. The last model that Bossi has produced is simply a four-branched uterine dilator with a strong screw on the handle and an indicator to show the amount of dilatation. Numerous dilators have recently been put on the market, and they all embody the same principle as the dilator of Bossi, and vary only as to detail of mechanical construction. J. B. DE LEE (Am. Jour. of Obstet., July, 1903) cites the following as the result of its application on three cases and a study of those to be found in the literature: (1) There is a small field of usefulness for the instrument in cases where rapid delivery by dilatation of the cervix is necessary after effacement. Before effacement, the colpeurynter should be used. It will be more successful in multiparæ. (2) The instrument would be useful in dilating the cervix in those cases where manual dilatation would be successful. It possesses advantages over the hand in asepsis, and that it is not tiring, so that the operator may carry out the subsequent delivery with comfort. (3) The instrument is not safe, but requires careful and skilful watchfulness, and one must search for and be ready to repair more or less extensive lacerations. These are greater in primiparæ. (4) It should never be used in placenta previa. (5) It does not replace the colpeurynter, the use of the hand, or cervical incisions in all cases.

**Abdominal and Vaginal Cæsarean Section.**—These most fortunately, are very rarely indicated for accouchement forcé. J. C. WEBSTER (Am. Jour. Obstet., July, 1903) finds that it was Acconi in 1895, who first performed vaginal Cæsarean section for the purpose of rapidly delivering the child, but that it was mainly due to Dührssen's advocacy that it has now begun to attract notice. When an eclamptic dies, the fetus being alive in utero, it is the duty of a physician who may be present, at the time of death, to advise immediate post-mortem Cæsarean section. Bauer has recently reported eight cases in which four of the infants were saved. Within the last few years, abdominal Cæsarean section has been carried out in placenta previa. It was first suggested by Lawson Tait. It must, indeed, be considered as rarely indicated in this condition, practically only when some condition exists which renders the other means or methods extremely hazardous or impossible. The writer has reported one case of a young girl of fourteen, in which excessive hemorrhage associated with a small vagina and a contracted pelvis necessitated the operation. Cæsarean section has been rarely employed in cases where there had been a premature detachment of a normally situated placenta though certain authorities so advise its use. Vaginal Cæsarean section is indicated in cases of accidental hemorrhages where the patient's condition is critical and where the cervix cannot be rapidly dilated by ordinary methods, provided a competent operator is at hand. It is indicated in affections of the heart, lungs, kidney, etc., where the mother is in danger and rapid delivery is indicated. In these various conditions, it is well to do vaginal section where the cervix does not admit of easy dilatation. The abdominal operation should not be employed save where there is no possibility of employing vaginal section in a satisfactory manner. It is indicated where the mother is in articulo mortis. The abdominal operation is by far the simplest and quickest in such cases, for it can be performed merely with a knife and without assistance. The vaginal operation has been advised but it would take longer and assistance would be required.

**Rupture of the Uterus During Labor.**—The patient was a VIII-para who had been 1½ days in labor when BARANOFF (Prakt. Vratch, No. 24, 1903) was called to see her. The pains which had been quite strong during the first twenty-four hours suddenly ceased after sharp, sudden pain in the lower part of the abdomen. This was accompanied by some hemorrhage. The patient was found sitting in bed, with pale face and cold extremities, complaining of very great fatigue; pulse 80, regular but weak. Examination revealed a rupture of the body just above the cervix uteri, the fetus in the abdominal cavity, which was also full of blood clots. As the conditions surrounding the patient were such as to preclude any possibility of a laparotomy, a careful extraction of the fetus, preceded by a cautiously performed version, through the formed rent was accomplished without any special difficulty except as to the extraction of the after-coming head with the extended arms. The fetus was dead. Many of the blood clots were extracted by the hand. The patient stood the operation well (no chloroform, simply hypodermic injection of morphine), and suffered from almost no hemorrhage. The placenta was removed without difficulty. The site of the rupture was tamponed for twenty-four hours. The course of recovery was quite uneventful, and in six weeks the woman was able to walk about. The author examined the patient six months after delivery and found her perfectly well; no pains in the lower part of the abdomen; uterus somewhat enlarged, but painless; the body of the uterus flexed laterally, the cervix to the left and high. The first menstruation took place six months after confinement, and is at present quite regular.

**Effects of Toxemia of Pregnancy upon the Cardiovascular System.**—Post-mortem lesions have been found in almost every organ in eclampsia. Thus punctate hemorrhages and areas of cellular necrosis found in the liver, the liver cell emboli, the thromboses, and emboli of giant cells, the dissolution of the blood and the destructive effects upon the blood vessel walls, the areas of gangrenous pneumonia found in the lungs, the hemorrhagic foci in the brain, and most constant of all lesions—the various pathological changes so frequently found in the kidneys—emphasize the fact, says RICHARD C. NORRIS (Am. Jour. of Obstet., July, 1903), that eclampsia cannot be attributed to any cause manifesting its destructive force on any one organ, but on a number of organs, with toxemia as an important factor in the etiology of that disease. One of the most valuable signs of a threatening outburst of eclampsia is a change in the tension and rapidity of the pulse. It may be presumed that when toxins have accumulated in sufficient strength to produce their first effect, that of irritation, the vasoconstrictor nerves are stimulated and a high tension pulse follows. When the accumulated poisons are finally sufficient to overwhelm the patient, the pulse tension falls, and wholly disappears in a fatal case. It is a well-known fact that when pregnancy is complicated by organic heart disease, the appearance of toxemia renders the prognosis for the heart lesion more grave, since there are such widespread changes induced by toxins, it must not be expected that the heart muscles will escape. There is no doubt in the writer's mind but that some cases of sudden death after labor can be explained by unrecognized toxemia originating during pregnancy and suddenly declaring itself by what the author calls "cardiac eclampsia."

**Cysts of the Round Ligament.**—The origin of cysts in this locality is, according to A. BROTHERS (Am. Jour of Obstet., July, 1903), ordinarily attributed to a persistence of the canal of Nuck. A serous cyst is formed by the gravitation of serum from the peritoneal cavity, through the open canal of Nuck in the direction of the labium majus. As the opening at the internal abdominal ring may be patent or shut off, two varieties of liquid accumulations may result—the one being a reducible, the other an isolated collection of liquid, *i.e.*, a cyst. Weber suggested that as the gubernaculum

of Hunter, which becomes the round ligament in the female, is at first hollow, and there might be a persistence of this fetal condition favoring a pathological growth. The occasional association of these liquid collections in the inguinal region with hernia has been made use of to explain the pathogenesis of these cysts of the round ligament. While a few observations have been made to sustain this view, the majority of cases point in the other direction. So that the simultaneous existence of hernia must be regarded as an occasional coincidence. These cysts of the canal of Nuck usually occur during the child-bearing period, especially between the years of thirty and fifty. The sac is lined with a single layer of epithelium (pavement) and may sometimes show muscular fibers. The tumor develops in contact with the round ligament which is usually behind it. It may have a pedicle extending to the inguinal canal which may be patent and communicate with the peritoneal cavity. The diagnosis is sometimes quite difficult because, if the cyst be tense, it may closely simulate a solid tumor. It would probably be most often mistaken for a hernia. Tympanitic percussion rate and irreducibility, excepting in strangulated or incarcerated cases, will usually exclude this condition. The presence of fluctuation and dulness on percussion, with an absence of pain and interference with the normal function of the bowels ought to make the diagnosis fairly easy. With active inflammation going on the diagnosis is not so easy, as under such circumstances many of these cases have been mistaken for incarcerated hernia. The treatment of these cases formerly consisted of puncture with the subsequent injection of irritating chemicals, such as tincture of iodine. Inasmuch as there may be a communication with the abdominal cavity at the internal abdominal ring this method of treatment is obviously associated with grave risks. In our present state of surgical science it is far safer to dissect out the cyst and to properly tie off the pedicle whether open or closed.

**The Breasts and Genitalia.**—Though the breast, the characteristic organ of mammalian animals, is anatomically and developmentally an appendage of the skin, still it is reasonable to consider it as part of the genital organs. As generally known, the breasts undergo great changes during gestation, the greatest degree of development in the time subsequent to parturition. It is a notewothy fact to which the attention of physicians has not as yet been drawn, and to the importance of which Ralph Temesvary (Brit. Jour. of Obstet., June, 1903) refers, that the death of the fetus during pregnancy without its expulsion from the uterus, such symptoms occur in the breasts as arise after delivery; the breasts become still more full and hard, and instead of colostrum they secrete real milk. These conditions rapidly recede and in a few days the breasts return to a state identical with that preceding gestation. From this change in the breasts, even Hippocrates inferred the death of the fetus in utero or impending miscarriage. Breast hypertrophy commences its evolution either at the period of puberty, simultaneously with the first menstruation, or during the first pregnancy; it is likewise in causal relation with the functions of the genital organs. Routh reports a case in a virgin where the breasts were hypertrophied as a result of masturbation. Regarding the new growths of the breasts, Lücke was the first who drew our attention to the fact that they sometimes occur during pregnancy, or if they have been present previously, then they commence to grow more rapidly. Cases have been observed in which women suffering from secondary amenorrhea had uterine hemorrhage in consequence of the irritation of the skin of the breasts. The sucking of the nipples during pregnancy may lead to uterine contractions and even produce abortion. Scanzoni has brought this result about by applying to the nipples a cupping instrument supplied with a rubber tube for suction, twice or thrice daily for two to three hours. In women suckling their babies involution takes place much more rapidly than if the child is weaned at birth. Indeed, if the child is suckled too long, the uterus may take on an hyperinvolution, or "lactation atrophy." This condition usually passes off after the child is weaned. In new growths of the breasts, particularly in cancer, not infrequently a secondary amenorrhea ensues. There may also be interruption of pregnancy. As to the nervous connection, first of all it may be mentioned that the lacteal glands are supplied with three kinds of nerves: sensory, vasomotor and motor nerves; these originate partly in cerebrospinal centers. Thus the lacteal glands stand in connection with the genital organs supplied with nerves coming partly from the sympathetic nervous system and partly from the cerebrospinal centers. The experiments of Mironow and Ribbert prove also that, not even the blood vessels form an indispensable path of communication between the breasts and the female genitalia, although the connection itself exists. Another way remains, and that is the presence of some substance secreted by the ovaries, which substance circulating in the blood of the suckling or pregnant female gives origin under certain circumstances to the secretion of milk. The writer holds this theory and further, that the blood circulation, the quantity of the blood flowing to the breasts, being influenced by the nervous system, plays only a secondary rôle. In the reverse direction the stimulus is chiefly produced by the nervous system, and the blood circulation here plays a secondary part in the form of a reflex hyperemia. In all these cases a certain outer stimulus, acting by way of the vasomotor nerves of the lacteal gland, causes milk secretion. Such stimuli are: attempts at suckling by infants, adults and animals; stimulating applications to the breasts, such as energetic counter-irritation, sinapisms, and vesicants.

**Congenital Absence of the Uterus and Atresia of the Vagina.**—In the case described by Dombrowsky (Prak. Vratch. No. 23, 1903) there was no other abnormality. The mammary glands were of normal size and form, well developed with normally pigmented areolæ. Mons veneris and labia majora well covered with hair. But the labia minora hardly developed at all; from the middle of the vestibule they gradually merge into the mucous membrane at the introitus vaginæ. Clitoris and meatus urethræ normal. In attempting to introduce the finger it meets a tough muscular partition which forms as it were a sort of a pocket that contracts over the finger, but presents no opening anywhere. This evidently served in coitus the purpose of an artificial vagina. The examination per vaginam failed to detect anything like a uterus, while bimanually both hands meet without the intervention of any body. Per rectum author succeeded in palpating a small roundish body of irregular form, easily movable and not tender to pressure or manipulation. The woman was twenty-one years of age, and has never menstruated, before or after marriage. As coitus was normal and painless whatever surgical interference might be indicated was not called for.

## NEUROLOGY AND PSYCHIATRY.

**Two Cases of Sarcoma of the Spinal Cord.**—Tumors of the cord, until recently cavities inaccessible to treatment, have of late excited considerable interest. Senator (Prakt. Vratch., No. 24, 1903) presents two highly instructive cases. In one case, that of a woman,

sixty-nine years of age, there was a history of ten months' duration, that began with a sensation of formication in the toes and pains in the feet; to this was later added inability to flex the knees, burning and pains in the soles which spread upward to the hip-joint. During the last six months patient lost all power of locomotion, suffered from convulsive twitching in the lower extremity, at times so pronounced and painful that the knees were forcibly flexed over the chest. There was also retention of urine. Patient lies recumbent on the back and is unable to move the lower extremities. Passive movements also hardly possible. Knee reflexes very much exaggerated. Babinski's sign present. Percussion of the muscles calls out painful twitchings. Stroking of the soles or legs is attended with clonic contractions of the lower extremities and of the abdominal muscles. Abdominal reflexes absent. Sensation lowered in the lower extremities. This condition grew gradually worse until the sensation of pain and temperature entirely disappeared, while that of touch disappeared over a still greater area extending upward. Late in the disease there occurred curvature of the spine at the third lumbar vertebra. In the course of the disease the body of the patient grew, as it were, shorter, the chest approached the pelvis. The abdominal muscles were almost in a continual state of contraction. Dyspnea and attacks of tightness in the chest, Cheyne-Stokes' respiration and marked slowness of the breath (8 per minute) supervened. Lumbar puncture during the early period of the disease brought forth 10 to 12 cc. of a limpid liquid with but little albumin. After the second puncture 5 c.c. of one-half-per-cent. solution of cocaine was introduced into the subdural space with remarkable improvement in the contractures and pain which lasted for three hours. Of the drugs employed scopolamine (hyoscine) seems to have given the best results. The autopsy revealed a tumor of the dura mater, which was macroscopically seen to be a sarcoma. The second patient was admitted to the hospital with pains in the back, inability to move the legs and complaining of tormenting thirst. The trouble began seven months before with pains in the back, between the scapulæ, which would at times become so severe as to render her unable to work. Some four weeks before admission the soles began to swell; this was followed by swelling of the abdomen, while two weeks before patient became unable to move the left leg. There is no retention of either urine or feces. Patient recumbent on the back, indifferent, consciousness slightly impaired. Knee reflexes exaggerated, Babinski's sign present, and ankle clonus indistinct. It is rather difficult to pick up the patient, as the spinal column is quite stiff. Patient complains especially of pains in the legs. Autopsy (patient died on the third day after admission to the hospital) gave the following: the heart slightly hypertrophied, lungs somewhat adherent, the thyroid gland hypertrophied, full of cysts; the bladder distended, its mucous membrane covered with necrotic spots; ovaries thickened. The vessels of the brain markedly calcified, the spinal column much congested, in the region of the third and fourth thoracic vertebræ to the left there is seen a hard swelling, which is macroscopically a fibrosarcoma. The interesting feature of this case is the very rapid course of the disease. The first stage, what the author calls the stage of neuralgia, was quite short, while the stage of paraplegia that usually occupies months and years, was hardly extended over two weeks.

**Chorea in Pregnancy.**—It has often been observed that the movements of a choreic patient are closely akin to those normally employed in the expression of emotions. In a young child, before the highest centers have developed co-ordinating control, such movements are alone present; it is only by a process of education that spontaneous movements of early infancy become coordinated, and thus capable of purposive action, says Cecil Wall (Brit. Jour. of Obstet., June, 1903). Rheumatism is undoubtedly, in the majority of cases, associated in some way with the chorea of childhood. So, too, during pregnancy, rheumatism plays an important part in the etiology of chorea. Buist found a personal history of rheumatism in 45 out of the 226 cases that he analyzed. The author's statistics show that at least 16 of 37 patients had previously suffered from some form of rheumatism. Twelve more had had chorea in childhood without other rheumatic manifestations. Antecedent chorea may suggest a rheumatic taint, but cannot be taken as conclusive evidence. In pregnancy, defective mental development seems to vie with rheumatism and previous chorea as one of the predisposing factors rendering a patient liable to an attack of chorea. The determining cause for chorea is not infrequently to be found in worry, for which the pregnancy is the chief cause; in case the patient is worried by the knowledge that her child is illegitimate. Fear of dystocia may be another inciting factor. Chorea in pregnancy seems to be determined by mental display, overstrain and shock. Secondly, the determining cause is only effectual when it acts upon a brain whose power of control is somewhat lowered by the pregnant state, and in addition is unstable in consequence of (1) antecedent chorea; (2) antecedent rheumatism or a similar debilitating condition; (3) a defect in development.

## PHYSIOLOGY.

**Influence of the Auricles on Cardiac Percussion.**—No systematic attempt has been made to ascertain the effect of the enlargement of one auricle upon the other or upon the heart as a whole, and the part they play in modifying the percussion boundaries has been generally lost sight of. With this point in view, D. R. Patterson (Bristol Med. Chir. Jour., June, 1903) has examined a large number of frozen sections in dogs and also a case of mitral disease in a human subject, and found that the auricles play a not unimportant part in modifying the relations of the heart. The investigations go to show that, while enlargement of the left auricle may take place to some extent downward, and possibly slightly upward, the chief increase is undoubtedly in an anteroposterior direction. This carries the heart forward and tends to influence the precordial area of dulness.

**The Gastric Secretion of the Newborn.**—The researches of O. Cohnheim and F. Soetbeer (Hoppe-Seyler's Zeitsch. f. Physiol. Chemie, Vol. 37, Nos. 5 and 6) show that in dogs no more than one day old, there is an active gastric juice containing free hydrochloric acid, pepsin and rennin. This secretion is reflexly accelerated by the act of sucking, independent of the presence of milk in the stomach. The authors were unable to determine whether any gastric juice is present in the pup's stomach before it has begun to suck or not. There are two facts of marked significance connected with the above results, namely: (1) The gastric juice of the nursling contains at the very earliest stage free hydrochloric acid and not lactic acid, as has been maintained; (2) The nervous mechanism controlling the secretion of gastric juice is at the outset of life an inherited reflex, initiated by the act of sucking.

**Compressed Air and Respiration.**—As the results of a series of experiments on mice, L. Hill and J. J. R. Macleod (Jour. of Physiol, June 16, 1903) found that compressed air at a pressure of +4 atmospheres and upward markedly diminishes the $CO_2$ output, very greatly lessens the $H_2O$ output and increases the loss of body heat. The lessened $CO_2$ output is due to the

high partial pressure of oxygen, which arrests the oxidative processes in the tissues. A partial pressure of 100 per cent. atmosphere of oxygen has this effect and the effect increases with the partial pressure. The $H_2O$ output is arrested because moist air when compressed becomes saturated with water vapor, compressed air delays evaporation by hindering the diffusion of water vapor and the escape of water vapor per liter during ventilation varies inversely as the pressure in the chamber. The loss in body heat is due to the increased conductivity of dry compressed air and of air saturated with water vapor. Wet air at one atmosphere and 20° C. increases tissue combustion in mice by increasing the loss of heat. The loss may be greater than the gain, so that the mice are cooled and may even die when long exposed to a current of wet air at temperatures below 20° C.

**The Functional Changes of Mammalian Muscle in Asphyxia.**—This frequently investigated theme acquires new interest at the hands of C. LHOTAK v. LHOTA (Pflüger's Archiv f. Physiol., Vol. 94, Nos. 11 and 12). He found that poverty of oxygen rapidly lowers the working power of mammalian muscle, sometimes to the zero point. A similar diminution of irritability also occurs if the muscle during asphyxia is at rest. The reduction of working capacity is at any rate transitory, for a muscle is capable of performing a long series of contractions for a long time after the cessation of heart-action. It thus appears that ability to manifest energy recovers spontaneously to a certain degree, which recovery can be hastened by mechanical stimuli and particularly by a renewed supply of oxygenated blood. By the latter means the asphyxiated muscle can attain its original power of contractibility. In the muscles of weak, lean animals and even after repeated asphyxiation, there appears to be little or no diminution of functional capacity.

**The Intestinal Absorption of Iron.**—The rule that in the intestine compounds soluble in lipoids undergo intra-epithelial absorption, while compounds insoluble in lipoids undergo inter-epithelial absorption, finds, according to R. HÖBER (Pflüger's Archiv f. Physiol, Vol. 94, Nos. 5 and 6), an exception in the case of iron. Starting out with the supposition that it is not an iron salt that enters the intestine and undergoes absorption there, but some iron compound formed in the stomach by union with albumin or albuminous decomposition product, which compound is soluble in lipoids, and hence, on this hypothesis the presence of iron in the epithelial cells would be explained, the author tried to discover if any other metallic salts which react with albumin or its derivatives similarly to iron, are absorbed intra-epithelially. This was found not to be the case. Neither salts of silver, mercury, lead, bismuth, copper, cobalt, nickel, nor manganese can be discovered in the intestinal epithelial cells; they are evidently slowly absorbed inter-epithelially as salts insoluble in lipoids. It thus appears that there are special provisions in the intestine for the absorption of iron.

**Lactic Acid Fermentation.**—For a long time engaged in the inquiry as to the real extent to which fermentative processes may be distinct from the life of cells, R. O. HERZOG (Hoppe-Seyler's Zeitsch. f. Physiol. Chemie, Vol. 37, Nos. 5 and 6) at last succeeded in obtaining from a culture of lactic acid bacteria, a powder which is capable of converting milk sugar into lactic acid. The reaction is a very slow one and the quantity of lactic acid produced is so small that it can be detected only by microchemical means.

**The Mechanism of Phloridzin Glycosuria.**—In confirmation of the results of Zuntz, F. W. PAVY, T. G. BRODIE and R. L. SIAU (Jour. of Physiol., June 16, 1903) found that the injection of phloridzin into the renal artery of one side produced glycosuria from the corresponding kidney prior to and to a greater extent than from the other. The perfusion of a surviving kidney with blood containing phloridzin, produced a diuresis accompanied with the presence in the urine of a notable amount of sugar, which is not to be accounted for by the disappearance of sugar that occurs from the blood. The intravenous injection of phloridzin produces glycosuria after ablation of the abdominal viscera (necessarily the kidneys excepted), and the elimination of sugar persists after the blood sugar has fallen to the lowest level that is noticed to occur. The sugar excreted under these circumstances may far exceed that existing in the circulating blood. The fall in sugar observed after simple ablation of the viscera undergoes no variation with the supplemented administration of phloridzin, notwithstanding the associated glycosuria. The hitherto proposed theories of phloridzin action fail to meet the requirements of the conditions existing. Under the view propounded by the authors, the glycosuria effected by phloridzin, is attributable to a special action exerted upon the cells of the renal tubules by which they acquire the power of producing sugar. They believe that under the influence of the presence of phloridzin, these cells exert a catabolic action upon something reaching them from the blood, resulting in the liberation of dextrose in a manner comparable to that by which lactose is set free by the cells of the mammary gland.

**The Rôle of the Liver and Spleen in the Destruction of Blood Corpuscles.**—A series of experiments were undertaken by W. BAIN (Jour. of Physiol., June 15, 1903), for the purpose of determining the changes which occur in the blood when it is passed repeatedly through the liver and through the spleen, and then of determining the influence of these organs upon the blood corpuscles. In a series of survival experments on the liver and spleen, it is shown that these organs retain the power of destroying the red and white corpuscles of the blood. The action of the liver is mainly one upon the red corpuscles, those poor in hemoglobin being the ones chiefly affected, a fact proved by the increased hemoglobin value of the corpuscles after perfusion. Of the hemoglobin set free, most is retained by the liver and further destroyed, since the loosely combined iron of the liver, as determined by the ammonium sulphide test, is largely increased after perfusion; since the amount of iron in the dried liver rises from .14 per cent to .26 per cent., and since the liver secretes a considerable quantity of bile rich in pigment during the course of the experiment. The main action of the spleen is upon the leucocytes, which are largely destroyed by it during the perfusion. The variety chiefly affected is the polymorphonuclear. The spleen in addition destroys a small percentage of red corpuscles, since their numbers are diminished, their hemoglobin value increased, and loosely combined iron is found in the perfused spleen in a greater amount, than in the normal spleen. In these survival experiments on the spleen, the nerves retain their excitability for a very considerable time after removal of the organ from the body.

## EYE, EAR, NOSE AND THROAT.

**Hay Fever Toxin and Antitoxin.**—The interest which has attended the experiments of Dunbar of Hamburg with the toxins and the antitoxins of hay fever, has prompted investigations by other observers. Semon of Berlin has already corroborated Dunbar's results from the clinical standpoint and a further report has lately been published by P. MCBRIDE (Edinb. Med. Jour., July, 1903). The experiments were conducted in six individuals, four of whom were subject to hay-fever.

Three of these gave very typical reactions, but one case was refractory. The latter had undoubted attacks of hay-fever, but also experienced similar attacks during the winter, of unknown origin. Although Dunbar has probably isolated both a toxin and antitoxin, the author believes that clinically there are numerous cases in which the theory that hay-fever is caused by the pollen of grasses only does not afford a satisfactory explanation. He has observed cases in which the attacks came on as the result of atmospheric conditions, such as the time of a hoar-frost and also mentions an instance where the attack came on the patient as he came in contact with horses independent of the season. The clinical use of the antitoxin is still sub judice.

**Otitis Media in Infancy.**—The frequency of this condition in infancy and its importance in differential dagnosis is insisted on by J. L. Morse (Jour. Am. Med. Asso., July 18, 1903). In all doubtful cases the ears should be thoroughly examined with a speculum. In many instances there is no sign of pain or many may have pain somewhere but show nothing by their actions by which the seat of the pain may be determined. Tenderness on pressure over the mastoid is also a very unreliable sign, as it is unusual in simple acute inflammation of the middle ear and most sick babies will cry if pressure is made on any part of their body. Acute otitis media is usually associated with fever, and reflex symptoms such as convulsions are not uncommon and may lead to a diagnosis of meningitis, pneumonia, gastritis, worms, dentition, etc. It is most commonly mistaken for pneumonia. A case so diagnosed and also another in which the symptoms seemed to point to cerebral trouble, are reported by the author. Acute secondary inflammations of the ear are more common than the primary ones, and occur as complications especially of diseases of the upper part of the respiratory tract. They are also common in diseases of malnutrition. Although the trouble may cause some symptoms, it may also go on perforation of the drum membrane without producing any symptoms whatever. The matter suggests the routine examination of the ears no matter what the disease.

**Treatment of Laryngeal Tuberculosis.** — Every methods of treating this condition in order to be attended by favorable results must reach the deeply infiltrating lesions of the disease. In accomplishing this it is also desirable that it should be done without causing any extensive injury to the overlying mucous membrane, on account of the possibilities of a secondary infection. L. Grunwald (Münch. med. Woch., June 23, 1903) recommends for this purpose the employment of the galvano-puncture, which he applies in the following manner: after proper anesthetization of the larynx, a very fine platinum cautery point is applied to the area of infiltration, and when it becomes incandescent, it is gently pushed down into the tissue. When the infiltrated area rests on healthy tissue, the latter affords a feeling of resistance to the further progress of the cautery point, and the latter must not be pushed any further. If the infiltration lies free and unsupported, the penetration of the needle is indicated by a red glow in the trachea. As soon as the point can be freely moved about in the tissue, it may be withdrawn. The procedure usually lasts from 5-10 seconds. The reaction is remarkably slight. In a few cases a small degree of swelling was observed in the surrounding parts, but pain was rarely present. In a few severe cases, some dysphagia was noticed, and in others in which a previous dysphagia had been present, it immediately disappeared. The author also remarks that this procedure is not necessarily limited to tubercular infiltrates, he also employed it successfully in an advanced inflammatory hyperplasia.

## THERAPEUTICS.

**Local Treatment of Diphtheria with Antidiphtherin.**—The belief held by a certain number of clinicians that Loeffler's bacillus does not gain access to the blood or internal organs but remains localized at the site of the diphtheritic lesion, is shared by M. Aramian (Jour. de Méd. de Paris, June 28, 1903). He therefore deems it more logical to attack the organism through local application rather than seek to neutralize its toxins through injection of serum. Excellent results are reported by the author from the use of a preparation to which he gives the name of antidiphtherin, the composition of which he intends shortly to present to the French Academy of Medicine. The remedy is applied with a swab three to six times daily; the tonsils, larynx, nasal fossæ, etc., being readily reached by this means. Of fifty-three cases so treated in his private practice, there were but two deaths; and these he attributes to complications which had developed prior to the application. For his method of treatment he claims absence of the dangers sometimes attending serum-treatment, facility of application, the possibility of preserving the preparation almost indefinitely, a recovery as rapid and probably more certain than with serum-treatment and early disappearance of the bacilli from the affected part; thus rendering prolonged isolation of the patient unnecessary, and greatly reducing the liability of contagion.

**Sciatica Cured by Local Injection of Antipyrin.**—Success is reported in the treatment of what the author calls primary sciatica—that is sciatica induced by causes acting directly upon the nerve, such as strain of the leg through excessive fatigue, cold, etc.—with hypodermatic injections of antipyrin in the course of the nerve, by P. Adolpho (Gazz. Osped., June 28, 1903). By means of a Pravaz's syringe provided with a long needle, 15 minims (one c.c.) of a solution containing 1¼ drams (5 grams) of antipyrin and 2½ drams (10 grams) of water, was injected at a point midway and slightly above a line reaching from the tuberosity of the ischium to the great trochanter; the needle being thrust in deeply till the nerve was reached. These injections, given daily, were entirely painless; and at the end of a week, pain ceased entirely in one case, and after ten days a like relief was experienced in the second. Two months having passed without a recurrence of the trouble, the author feels justified in considering the cure a permanent one; and concludes that in rebellious cases of sciatica which, as in the two cases reported, resist other methods of treatment, injections of antipyrin should be tried.

**The Action of Adrenalin.**—As a result of a series of investigations and experiments on the action of adrenalin, Simonovich (Roussky Vratch., No. 24, 1903), arrives at the following conclusions: (1) The drug, in the doses employed, exerts a general effect only when injected into the blood; (2) introduced per os in quantities far exceeding the maximum therapeutic doses (0.01) it fails to produce any subjective feeling; (3) the failure to exert a systemic action is due not so much to the action of the liver as to the slow absorption of the adrenalin, for injections into the intestinal veins produce an effect from comparatively small doses; (4) injuries of the gastro-intestinal mucous membrane do not increase the absorption of adrenalin; (5) the application to mucous membranes, *e.g.*, to stop gastric hemorrhages, is not attended with any systemic toxic effect; (6) the maximum dose may be considerably increased if the drug be administered for its general effect, but in the local application the frequency of the application is more important than its dose; (7) glycosuria from adrenalin is evidently due to toxicity.

## SUICIDE AND SYPHILIS.

Almost every physician in general practice has felt at some time the strain of terror over the possible effect of his words to some unfortunate youth. To cite an imaginary case which is by no means imaginary. A well-favored young man consults him to know whether he is in a position to announce his engagement, or to set the date of his marriage. The physician bound by a moral code tells him that he is syphilitic and cannot safely marry for several years. The youth shows shock, or horror, or despondency, and mutters that he might as well make an end of the whole thing at once. The physician cheers and encourages him, and thinks he has fortified his hopes. The youth departs pledging his one confidant to secrecy. A few days pass, his parents come. The son has disappeared. A last note mentions a necessary journey, but letters fail to bring a response. Can the physician give any clue? The parents are naturally in an agony of uncertainty, but does not the physician guarding the boy's secret, and dreading to read the morning papers suffer more than justice should permit? If, as is often the case, the journey is but the spasmodic effort of the young man to hide himself and his shame, time relieves the physician's anxiety as well as effects his patient's cure. But if it happens, as it does too frequently to be ignored, that the boy ends his life with a revolver, or a gas-tube, the physician will always feel that he is responsible, although without blame, for the suicide.

Conan Doyle, in his collection of medical tales "Around the Red Lamp," discusses the situation. There the victim of hereditary syphilis tells the specialist who makes the diagnosis that he is on the eve of wedding a well-known society girl. The next morning the physician reads in the list of casualties that his patient was *accidentally* killed while crossing the crowded avenue the evening before.

The question of the physician's responsibility is a moral and not a legal one, and yet it is worthy of serious consideration. M. Alfred Fournier, in a recent communication to the *Bulletin de l'Academie de Médecine* (July, 1903) quotes a number of suicides which were traced either directly to the physician's diagnosis or to the patient's fears that such was the real nature of his disease. In presenting the subject from his own experience as well as collecting instances from his confreres he broadens the subject to a general discussion of Suicide in Syphilis. He mentions cases where, as a result of syphilis, the patient has developed mental trouble, and commits suicide because he has become insane or intensely nervous, and classes with these the patients with a neurotic tendency, as the result of inherited syphilis, who are naturally predisposed to suicide.

In a second class he cites instances of persons who have committed suicide because of the loathsome conditions of their disease, or because they feared such consequences. In a third class he cites the cases of those who, from honor, or shame, or shock that upsets the reason, or fear, commit suicide immediately on learning the physician's diagnosis, and in the fourth class he places those patients who, because of the social aspect of their disease, being about to be married, or to return to their homes, thought it the only honorable solution thus to end their lives.

Unquestionably many of the inexplicable cases of suicide are due to the greed of those sharks that advertise in the lay and religious press, who under the guise of regular physicians, diagnose and offer to cure (confidentially) diseases which the young as well as the married are ashamed to take to their regular family physician. To heighten the necessity for such treatment, these "Old Doctor Blanks" paint the most lurid horrors if treatment is not immediately begun.

Casting out, however, the methods of the un-

professional the question is, "How shall the physician best guard society from infection, and at the same time consider the individual's point of view."

Undoubtedly it is his duty to impress the many avenues of contagion upon his patient, as well as to forbid him to enter into any marriage relation, but at the same time it is his duty to arrive at the point slowly and to point out every encouraging feature.

M. Alfred Fournier, from his own experience, as well as from the experience of others, has come to the conclusion that it is unwise for the practitioner ever to make his diagnosis abruptly. No matter how sure he might be that a chancre was syphilitic, he should at first lead the patient to believe that an exact diagnosis could not be made at present, and not until after accustoming him by degrees to the possibility of the disease and to its most hopeful outcome should he by the third interview admit that the disease was syphilitic.

It is the first shock as a rule that counts with patients, and the susceptibility of the individual to his own moral sense is something that the physician cannot count upon, even though the patient be his friend.

---

## RADIUM IN THERAPEUTICS.

In our account of recent advances in the scientific knowledge of radio-active elements we suggested the possibility of the importance of these metals in therapeutics and especially in the treatment of malignant diseases, as soon as the expense of the present difficult methods of preparation had decreased to such an extent as to make a sufficient quantity of the metals available. It seems that our prophecy in the matter has proved true even before any great reduction in their price. The energy produced by the radio-activity of radium particularly is of so intense a character that even with the minute quantities of it which physicians are able to obtain some very interesting results have been secured. The cable reports of the past week show that in Vienna the metal radium has been used with excellent effect on a number of patients suffering from the most intractable forms of malignant disease. We sincerely hope that these preliminary reports will be confirmed by further details.

Patients have been presented before both the prominent medical societies of Vienna, the Society of Physicians and the Imperial Academy of Sciences in whom cancer has been cured, at least for the time being, by exposure to the rays of radium.

As we suggested in our previous editorial the effect of radium upon the external layer of cells is such that after an exposure of a few hours a slough ensues and the resulting ulcer is so difficult to heal that it is very evident that the trophic nerves to the part have been interfered with. As a malignant neoplasm is after all an exhibition of hypertrophy of tissue under the influence of some irritant, be it a parasite or something else, or is due to a disturbance of the normal vital relations of cells to one another with the consequent production of a cell insurrection, as it were, it is evident that the disturbance of the trophism of the part may well prove the secret of the natural cancer cure. This is probably the way in which the mixed toxins act, when they produce their wonderful curative effect.

The first patient presented to the medical societies of Vienna was a man of sixty-one, who had suffered for many years from cancer of the lips, which in spite of numerous operations had not been eradicated, but had eventually invaded the palate. This invasion had become so extensive that during the early months of the scholastic year 1902 the surgeons had pronounced further surgical treatment as likely to prove fruitless. Under these circumstances the use of radium was suggested and a very minute portion of the bromide salt of radium was obtained. This is the purest form of the material as yet available, and it is said that only a very minute portion, a few milligrams, scarcely more than a tenth of a grain, were employed. The malignant condition gradually healed and for some time has ceased to give any manifestation of activity.

At the last meeting of the Imperial Academy of Sciences of Vienna to which this patient was presented, further reports of the use of radium in the treatment of malignant disease were made. In one case a cure seems to have been effected in that most obstinate of all forms of malignant neoplasm a melanosarcoma. Of course it can be readily understood that such reports are only preliminary. Until at least three years have passed there must remain a question in the mind of serious physicians of any radical cure of cancer. The relief afforded by radium, however, seems to be exactly of the kind which is produced by the X-Rays, only the radio-active metal has the advantage of producing more intense and rapid effects and seems also to be more generally applicable than the X-Rays have proved to be. It is easy to

understand that the first reports are apt to be tinged by hyperenthusiasm, but a definite announcement that a new therapeutic agent is at hand is surely justified by what we know up to the present time.

From another important scientific body, the department of General Pathology in the Imperial Russian Institute of Experimental Medicine at St. Petersburg, there comes a further encouraging report with regard to radium in therapeutics. Dr. London, whose contributions to the discussion at the recent International Chemical Congress in Berlin attracted no little attention, has been defining the limits of the effect of radium upon the optic nerve by a series of very interesting observations. Ordinarily the crystalline lens, which by its concentrating action on light aids vision by means of light rays, rather prevents the action of radium rays upon the retina. This is not surprising, since many perfectly transparent substances act in just this same way, with regard to the X-Rays. On the other hand, where the lens is obscured or even where the optic nerve is degenerated, light impressions are produced by means of radium. In one case under Dr. London's observation an eleven-year-old boy, who had been blind from the end of his first year, as the result of atrophy of the optic nerve, has learned to recognize letters traced on screens with radium and to put together the letters thus formed into words.

It seems clear then that we are on the threshold of a new and perhaps far-reaching advance in therapeutics. It will not be long before other reports will bring confirmation of at least some of these results.

---

### THE CASE OF BUBONIC PLAGUE IN BERLIN.

As the details of Dr. Milan Sachs' death while at work on the bacteriology of the bubonic plague reach us, some interesting facts are brought prominently to our attention.

Our readers undoubtedly remember the death, in 1898, of Dr. Müller at Vienna, who fell a victim to "laboratory" plague, after having spent considerable time in India where he studied the disease through daily contact with pest-stricken patients. So profound was the impression produced by this tragic death that the Austrian authorities forbade henceforth any experimentation on the plague bacillus within the domains of the kingdom. Dr. Sachs was commissioned, by the same Austrian Government, to conduct his investigations at the Koch Institute in Berlin.

It appears now that this ambitious and highly gifted young scientist, while filling his Pravaz syringe with pus from an infected guinea pig for the purpose of transferring it to the culture medium for colonization, had the misfortune of admitting into it a few air bubbles, and in forcing the pus out a drop of it sputtered over him, and thus became the starting point of infection.

The disease manifested itself on the fifth day, examination eliciting an ordinary pharyngeal congestion, a few swollen glands, slight apical dulness of the lungs and a few moist râles. However the marked feature of the case was the striking disproportion between the slight local symptoms and the grave general condition of the patient, as manifested by a high temperature, extreme prostration, etc. Unfortunately for the patient, through faulty arrangement, he was not conveyed at once to an isolation hospital, and when finally transferred there was in an unconscious condition. Meanwhile the diagnosis, both clinical and bacteriological, dissipated whatever doubt had been entertained as to the character of the affection (the pneumonic form of the disease is not at all typical of plague, and may be mistaken for bronchitis, broncho-pneumonia or croupous pneumonia), but by this time the unfortunate sufferer was beyond human help. The autopsy showed those of typicalwhen the manod also those of pulmonary tuberculosis. Of those who came in contact with the deceased, a hospital orderly suffered a mild attack of the disease evidently modified by the injection of the prophylactic anti-bubonic serum. The physicians and other attendants on the case received similar injections, while strict measures for isolation and immunization were adopted toward all who came in any relation with the case.

The question of following Austria's example by prohibiting any laboratory experiments and study on the plague bacillus in Germany was agitated in the lay as well as in the medical circles, but the prevailing opinion was in favor of continuing this most valuable laboratory work. The biology of the plague bacillus is as yet but little known, and the problems of immunity, and the production of a sufficiently strong anti-plague serum require a great deal of earnest study. The rarity of the disease precludes any possibility on the part of the average physician to diagnose its early stages, and laboratories where trained diagnosticians may pursue their studies are of great importance, especially for seaports, which are most of all liable to the dangers of infectious diseases.

As regards Dr. Sachs' case, it must be recognized that his general vitality was lowered by tuberculosis, and his resisting powers to infection accordingly reduced. A suggestion was made that in the future an applicant's physical fitness for laboratory work should be looked into with as much care as his scientific attainments, and while in the laboratory an examination of his physical state be made daily.

What is most instructive in the case for us, in view of the recent occurrences at San Francisco, is the remarkable attitude of the public in Berlin toward the whole affair, namely the entire absence of any panicky feeling to the population. This was principally due to two factors: the wide publicity, absolutely without any taint of sensationalism, given to it by the press, and the implicit confidence in the sanitary measures undertaken and carried out in a fearless and decisive manner by the authorities. The detailed daily reports on the doings of the sanitary board have more than anything else served to allay whatever apprehension might have been felt by the people. The results thus far show this to be the safest as well as the most rational method to be pursued by health boards in similar emergencies, and the conduct of the Berlin authorities will serve, let us hope, as an example to be followed by others.

## ECHOES AND NEWS.

### NEW YORK.

**Honor to Dr. G. R. Butler.**—Dr. Glentworth R. Butler, of Brooklyn, has been elected a life fellow of the Society of Science, Letters and Art of London.

**New Dean at Long Island College Hospital.**—Dr. J. D. Rushmore has been elected Dean of the Faculty of the Long Island College Hospital, in place of Dr. J. H. Raymond, resigned. Dr. Raymond was elected to succeed the late Dr. J. S. Wight.

**New Dispensary for Mt. Sinai Hospital.**—The Association of the Mt. Sinai Hospital has just purchased property in Pine street on which to locate a new dispensary.

**A New Possibility for Blackmail.**—A bill was signed by Governor Odell some time ago making it a misdemeanor to distribute patent medicines so that children may get at them. It should be borne in mind by physicians that after this they may be blackmailed by some enterprising crooks if they neglect to empty out all patent medicines preparatory to throwing them in the waste basket. Ostensibly the bill is to have for its purpose the protection of the children of ragpickers, etc., who, tumbling over summer ashbarrels, find boxes and bottles of death-dealing drugs within them. Tempted by the seductive colors and tastes, they go to their doom unmindful of the dangers lurking in the patent medicines. Still another avenue to blackmail the physician seems to have been opened and we counsel caution.

**Dr. Lederle in Favor of Abolishing River Baths.**—President Lederle of the Department of Health does not regard with favor the free municipal baths along the river fronts. He regards them as the primary cause of a certain amount of infectious disease among those who frequent them, and as dangerous to the general health of the city. Since the hot months began he has had a number of the bath-houses moved from their anchorages because of polluted water or other good reasons. In some cases it has been found necessary to put two houses at the same anchorage for lack of suitable locations. The question of getting rid of the river front baths and substituting plunges and shower baths of pure clean water is now being considered by the Health Department. Commenting on the subject to-day, Dr. Lederle said: "The floating baths along the river front, which are necessarily located in more or less sewer-polluted water, are probably the primary cause of a certain amount of infectious disease among those who frequent them. Thousands of persons patronize them during the summer months, but they do this rather for recreation than for cleansing purposes. During their baths they run the risk of taking in through the skin or inhaling or swallowing germs of infection of various diseases, such as typhoid fever, diarrheal diseases, consumption, and through contact chiefly, acute conjunctivitis (pink eye), and certain skin diseases. The average citizen has no idea of the enormous quantity of sewage which is dumped every day into the rivers which border this city. The sewers discharge at the bulkheads and under piers at the ends of streets, and the sewage is frequently retained for long periods by eddying tides, after which it may be carried to sea by the ebb, or may have time to settle into the slime of the river bed. With a constant flow of sewage, the marginal water is never uncontaminated, and therefore it is impossible to keep the water in floating baths other than unsanitary, if not positively dangerous. It is accepted as certain that more or less disease is yearly transmitted as a result of the condition of these baths, and their use has only been permitted and not advised by the Health Department during the summer season. In consenting reluctantly to the continuance of baths along the river front, the Health Department had in view the needs of the poor people for cooling and recreation during the heated summer, and there was, of course, the prospect that before another year sufficient provision would have been made by the city for free public baths in the crowded sections, where hot and cold fresh water would be provided, and the needs of the inhabitants for bathing met in that way. It is a matter of great satisfaction to learn that the city is proceeding with the construction of such baths, appropriations for which the Health Department has frequently urged upon the Board of Estimate and Apportionment. When enough of these baths have been provided, much will have been done in the way of prevention, through personal cleanliness, of the infectious diseases so frequently occurring among those whose homes lack proper bathing facilities. I venture to say that there is no greater public need in this city to-day than an adequate number of free baths."

**Unity of the Medical Profession.**—Dr. A. T. Bristow, President of the State Medical Society, said the following, among other things, at a recent address given before the Associated Physicians of Long Island:

"One of the most important things for the medical profession to-day is unity. Unfortunately, as you know, dissensions have existed in our ranks in this State for many years. Originating in a ques-

tion of principle, the strife has been correspondingly bitter. We wage war in behalf of a neighboring island, and victor and vanquished soon forget the brief animosities engendered, but it has taken decades to efface the recollections of the wars of religion. A battle for principle has many resemblances to the religious war. Such has been the battle of the code and each side has striven for the right according to the different points of view of the contestants. When I was elected President of the State Society last winter, the prospects of unity seemed remote. The question of the code was involved in much obscurity, and no one seemed to know just what its position was. Moreover, the State Association insisted as a *sine qua non* to union that the State Society should apply for a new charter together with the Association. This seemed to me the most insuperable barrier to union, for the State Society prized its old charter, now nearly one hundred years old, and refused to do anything that would cause it to lapse. This was a question of sentiment, to be sure, but let me remind you that many of the things that we hold most dear are matters of sentiment, that is to say, affairs of the heart rather than of the intellect. Patriotism is a sentiment, so is the affection of parents and children, and so is religion in so far as it concerns the heart rather than the head. Our most precious possessions are thus matters of sentiment, so it was not strange that the State Society should be unwilling to allow its ancient charter to lapse. We are but a young country. We have few associations with a remote past, and those that we have we should cherish. I do not believe that the Association appreciated this feeling, nor, perhaps, foresaw it. On the other hand, it seems to me a perfectly natural and proper feeling on the part of the Association that the members should wish for some legal recognition of the reunion. Otherwise, it would be necessary for them to abandon their organization and join the State Society as individuals, something, in my opinion, that the State Society will by no means expect. Inasmuch as both parties to the dispute of thirty years ago contended for principle as each saw it, neither side should now be penalized for the contention which is a thing of the past and feelings of mutual concession and toleration should prevail. All ought to try to assist those who are working for unity and not be on the lookout for unreasonable objections, with intent to hinder. It has seemed to me that it might be possible to draw up an act which should preserve the old charter of the State Society and add to this the desirable features of the Association charter and thus comply with the wishes of that body that some legal recognition should be taken of the new order of things. In this way neither organization would perish, but the two bodies would simply merge. Unification would, in this manner, be accomplished without loss of dignity on either side and the reorganization would take place as it ought, in a manner honorable to both the subscribing parties, and with undue advantage to neither. If the matter of the charter can be arranged on these lines, as I am sure it can, then there is nothing whatever to keep us apart. The code question has been forever settled by the liberal and progressive spirit shown by the American Medical Association and the profession of this State will be much to blame if it allow ancient prejudice or revived animosities to stand in the way of unity. It will not be long before this whole question will come up before the rank and file of both societies, and it will then become the duty of every man to see to it that nothing but matters of principle shall allow this breach in our ranks to continue. No such question exists. Every one recognizes that. All men say that we ought to unite. Let me then urge on every one here that it is an individual duty which will soon confront us. If you wish unity you can have it for it will be a question of the ballot. If you do not get it, do not blame the conference committee, nor the officers of the two societies. Blame yourselves, for there the responsibility must finally fall."

**Duty of Health Boards to Smallpox Patients.**—It is the undoubted duty of a town Board of Health, says the Fourth Appellate Division, by Presiding Justice Adams, in the case of Garra K. Lester against Joseph H. Eno and others, to take immediate and efficient steps, when smallpox develops within its jurisdiction, not only to furnish care and attendance to persons afflicted with the disease, but to protect, as far as possible, the residents of the town from the danger to which they are exposed by reason of its contagious and malignant character. To this end the Board of Health is authorized to incur any reasonable expense, and the expense thus incurred becomes a charge upon the town. The court therefore held that where the Health Officer of a town, acting under the authority of the town Board of Health, orally employs a physician to treat and care for all patients in the town who were then, or might thereafter be, afflicted with smallpox, assuring the physician that he would be well paid for his services, the town is liable to the doctor for the reasonable value of the services rendered by him.

## PHILADELPHIA.

**Increase in Typhoid and Smallpox.**—The cases of typhoid fever for the week ending August 1st numbered 109 as compared with 65 for the previous week. During the same period the new cases of smallpox were 29 as compared with 11 for the previous week. The mortality from the latter disease was only three, as against 11 the preceding week. One case of black smallpox in Port Richmond caused the vaccine corps to work in that neighborhood all day on Sunday. The death rate of infants shows a gratifying decrease, the deaths being the least of any week since the summer began.

**Phipps Institute Asks for Charter.**—The Phipps Institute for the Cure and Prevention of Tuberculosis has applied to Common Pleas Court for a charter. The work of the institute has grown to such proportions that the managers decided that a charter was necessary to enable the work properly to be carried out.

**Typhoid in Pittsburg.**—The epidemic of typhoid fever in Pittsburg still continues. During the six days ending August 1st there were reported 102 new cases of the disease, almost as many as during the preceding week. The city water supply is supposed to be the source of the disease.

**Result of State Board Examination.**—Of the 392 applicants for authority to practice medicine in the State of Pennsylvania, who were recently examined in this city and Pittsburg by the State Board of Medical Examiners, 339 were successful. Fifty failed to obtain the necessary 75 per cent. average; one was expelled for cheating and two withdrew because of illness.

**Pennsylvania Hospital.**—A committee of former resident physicians of the Pennsylvania hospital, consisting of Drs. James C. Wilson, Frank Woodbury and T. H. Andrews, has authorized the painting of a portrait of the late Dr. Thomas G. Morton. It will be a three-quarter length picture and is to be completed in November. At that time the picture

will be publicly presented to the hospital and hung among other portraits of those who have been honored in the medical profession.

**New Hospital to be Erected.**—It is stated that a new hospital, to be known as the Union Mission Hospital, is to be built by the John B. Stetson Company in Fourth street, below Montgomery avenue. The building is to be a fire-proof brick structure, three stories high and 65 by 102 feet in size. A roof garden will surmount the building.

**Deaths from Adulterated Milk.**—Two deaths at Johnstown, Pennsylvania, apparently traceable to the use of injurious drugs to preserve milk, have prompted State Dairy and Food Commissioner Warren to inaugurate a general movement against those who sell adulterated milk. Of 1,000 samples obtained in the Eastern and Western parts of the State, 75 per cent. contained formaldehyde or other similar fluid. A State laboratory for the examination of foodstuffs is soon to be installed in Harrisburg.

## CHICAGO.

**Licenses for Infant Nurseries.**—So far the city clerk has issued two licenses and permits to conduct infant nurseries in the city.

**Endowment of Free Beds in Hospitals.**—By the will of the late Horace P. Taylor, St. Luke's and the Chicago Baptist Hospitals each receive $9,400 for the endowment of free beds.

**Injunction Secured by Dr. Orsinger.**—Dr. Frederick L. Orsinger has secured an injunction restraining the State Board of Health, Justice Chott, and his constable from causing his imprisonment or enforcing a judgment of $100 and costs secured against him for violation of the medical laws.

**Diphtheria.**—Diphtheria is still prevalent, and the weekly number of deaths remains higher than usual for the season, but not to an extent warranting certain sensational statements recently published.

**Low Death Rate Among Aged.**—A phenomenally small proportion of deaths among the aged was one of the noteworthy features of a remarkably low July death rate for the week ending July 25th. There were only 55 deaths among those over sixty years of age reported out of the total, 513 at all ages, while the rate for the total—14.19 per thousand—is the lowest ever recorded for any July week in Chicago.

## GENERAL.

**In Honor of the Late Major Walter Reed, M.D.**—A meeting will be held at the Hotel Louisburg in Bar Harbor, Maine, on the morning of Saturday, August 15, 1903, at eleven o'clock, to confer with respect to a memorial in honor of the late Major Walter Reed, M.D., U. S. A., to whom the world is indebted for most important services in the investigation and the suppression of yellow fever. All of our readers are respectfully invited to be present. Several committees in different parts of the country have already been appointed, and the object of this conference is to secure unanimity of purpose, and concerted action. Addresses may be expected from gentlemen who are well acquainted with all the facts. In behalf of many friends of Dr. Reed,

Daniel C. Gilman,
Chairman of a Committee Appointed by the American Association for the Advancement of Science.
S. Weir Mitchell,
Edward G. Janeway,
William H. Welch,
Christian A. Herter.

**Mortality in European Armies.**—Official figures show that during the years 1888 to 1900 the mortality in the French army was more than double that in the German army.

**Tuberculosis in Europe.**—An official health report from Berlin states that in a million inhabitants, Russia has 4,000 tuberculous subjects; France and Germany 3,000 and England, Belgium and Italy 1,000.

**Pathogenesis of Tuberculosis in the Sixteenth Century.**—An Italian work, in which the author gives expression to his ideas as to the true method of propagation of tuberculosis, has recently come to light. This book is said to have been published in Venice in the year 1520, and was announced as "A new work entitled 'Why,' a useful volume for ascertaining the reason of many things." In this work the author makes the following statement: "From the sputum of the phthisical patient or from his mouth a fetid vapor arises, which, entering the mouth of the person with whom he is conversing, penetrates to the lungs and produces phthisis."

**Rhode Island Medical Society.**—The ninety-second annual meeting of the Rhode Island Medical Society was held in Masonic Building, Providence, June 4, 1903. The President, Dr. George F. Keene, presided, and about 150 Fellows and guests were present. Dr. Halsey DeWolf, Secretary, reported for the Trustees of the Caleb Fiske Fund: that the amount now at their disposal is $1,147.18. The prize of $250 for the best essay upon the subject, Auto-intoxication as a Cause and Complication of Disease, was awarded to Dr. W. Louis Chapman, of Providence, R. I. The subject chosen for the prize essay of the coming year, 1903-4, is the Action of Light as a Therapeutic Agent, and the amount of the prize offered is $250. It was voted to hold the next meeting in Newport, R. I. The following physicians were unanimously elected to Fellowship: Dr. Samuel Marsden Beale, Jr., Howard; Dr. Edward Campbell, Providence; Dr. William Francis Flanagan, Providence; Dr. Herman Canfield Pitts, Providence, and Dr. Henry Bertram Potter, Providence.

**Typhoid in Germany.**—It has been decided in Germany to wipe typhoid off the map and with this end in view most vigorous procedures are being planned by the Koch Central Bureau. Typhoid stations are being established throughout the German Empire with fully equipped laboratories and a well-paid staff of assistants. Every case of typhoid is to be tracked to its source and to be carefully isolated. The police force is at the service of the commission. Altogether the movement is both formidable and magnificent.

**Mosquito Destroyer to be Tested.**—Dr. Stiles will leave Washington, says the press agent, for Cape May or some other point in New Jersey where the mosquito rules, to pursue his researches into the efficacy of the parasite which it is said will exterminate mosquitoes by the million. The investigation to be made by Dr. Stiles is undertaken at the request of Prof. Smith, of Rutgers College, State Entomologist of New Jersey, who has aided Dr. Stiles in his search for the destroyer.

**Pure Food Law.**—The first tests under the recent law to prevent the importation of adulterated food are provided for in an order issued July 30, 1903, by the Treasury Department, authorizing the chemists of the Department of Agriculture to take for analysis samples of certain cargoes now on the way to American ports. The officers of both departments decline to state what these cargoes are or to name the vessels in which they are being transported, giving as a reason that if it were found on analysis that

the merchandise did not fall within the prohibition of the statute, harm would be done its owner by the attending publicity. Chief Chemist Wiley of the Department of Agriculture, under whose direction the tests will be made, said to-day that so far attention had been directed only against such products as spices, peppers, canned goods, cheese and other articles of the kind which had been under suspicion in the past. Declarations made before the American Consuls abroad concerning certain shipments included in the list named have already reached the Department of Agriculture, and as samples sent from the port of shipment could not reach the Department in time for the completion of the analysis before the entry of the cargo at the port of destination, the inspectors will meet the cargo on arrival and take the samples then. All the cargoes selected for analysis are now on the way. Declarations from abroad as to the purity of shipments are being received at the Department daily, some of them coming from the Orient. This work is being carried out by the United States Consuls, who notify the Department of all shipments of foodstuffs and transmit the declarations of the shippers.

**Electricity as a Therapeutic Measure.**—According to L. Guthrie (*Medical Magazine*, July, 1903) the first mention of electricity as a therapeutic measure is made by Salmon, an Englishman, in his book called "The Dispensatorie," which was published in 1676. He alludes to the use of the electric ray, torpedo or "cramp fish" in dropsy, consumption and headache. "The same helps the gout," says Salmon, "when trod on till the Stupidity reach the knee."

**Certified Milk as it is Made.**—The recent discussions on certified milk would seem to have borne excellent fruit, as witness the following from *Harper's Monthly*, anent the

"CRAFTY COW":

There was a Piper had a Cow.
And he had Naught to Give her.
So he pulled out his Pipes, and Played her a Tune—
Consider, Cow, consider.

The Cow considered Very Well.
"You've done the best You're able."
She said: "Now put my Halter on.
And lead me from the Stable.

"Take me to where the Health Board Sits,
That It may Certify
That You are You, and They are It,
And also I am I."

The Piper Did as he was Bid.
And When the Health Board Spied
A Decent Cow who had till Now
Gone on Uncertified—

It Waked and Wept
Where it had Slept,
And said, "We Certify
That you Are You,
And he Is he,
And also We are I."

From Then till Now
That Clever Cow,
Presuming on her Label,
Has made the Piper
Work the Pump,
And Lolled about the Stable.

**A Journal on Syphilis.**—We learn from the *Journal of Cutaneous Disease* that *La Syphilis* is the title of a new French monthly edited by Dr. T. Barthélemy to be devoted entirely to this special field of medicine. The first number contains an original article on syphilis of the stomach by Prof. Alfred Fournier; a clinical lecture on the same subject by Prof. Dieulafoy; a general program by the editor outlining the plan and scope of his new work; clinical lectures by Gaucher and Brocq; a department for brief notes on cases which in themselves might be considered of too little value to be published, but which in the aggregate would be of great value to special investigators; a department for correspondence in which replies are requested to a number of debated questions, such as "double infections," conceptional syphilis as regards the mother, pigmentary syphilides of the neck, etc.; a department of therapeutics and society proceedings, especially societies for venereal prophylaxis; and finally a special abstract and bibliographical department. We echo the best wishes of the editor of the *Journal of Cutaneous Disease* for the success of *La Syphilis*. May it accomplish much towards the prevention and cure of a disease which "although venereal in its manner of approach is not so in its manifestations." By boldly adopting as title a name so often shunned or stigmatized with moral obloquy, a long step is made towards placing syphilis beside leprosy and tuberculosis as one of the great plagues of mankind and with them fully entitled to a special organ.

**Insanity in England.**—The annual report of the Lunacy Commissioners shows an enormous increase in madness in England and in Wales. In 1859 the number of insane was 36,762, or one in 536 of the population. There has been a steady increase from that time up to January 1, 1903, when the number of insane was 113,964, or one in every 293 of population. The rate of increase since 1894 has been especially notable, the gain being from 92,067. There was never such an increase in the numbers of insane as in the year ended December 31, 1902, the increase over the previous year being 3,251. The number of persons who lost their minds in 1902 alone was 22,581, or almost 500 per week. The increase was found almost entirely among pauper lunatics. The proportion of lunatics privately cared for to the population is about the same now as it was in 1859, whereas the pauper proportion is twice as high. A carefully compiled table explains as far as possible the causes of lunacy. The list is headed by drink, to which 23 per cent. of male and 9.6 per cent. of female cases of insanity is ascribed. Heredity accounts for the greatest number of women lunatics, the proportion being the high one of 24.6 per cent. In the case of men, heredity accounts for 18.8 per cent. of insanity. Previous attacks come next with 23.1 per cent. of women and 16.2 per cent. of men. In cases of unknown causes, men come first with 17 per cent. and women follow with 15.4 per cent. The general impression that the increase of lunacy is due to the mental wear and tear of modern life is not supported by the figures. Adverse circumstances, including business anxieties and pecuniary difficulties, account for the lunacy of 6.2 per cent. of the men and 3.8 per cent. of the women; mental anxiety, worry and overwork, 5.7 per cent. of the men and 5.9 per cent. of women; love affairs, one in 200 of men and three in 200 of women. There is about the same proportion of insanity through fright and nervous shocks. According to the figures of the commissioners, physical, rather than direct mental causes are responsible for the great increase in insanity. One case in three can

be traced to some disease or disorder. The percentage of old people who have lost their minds is as seven men to eight women. The age limits between which the majority of patients are admitted to asylums are 25 to 44. One-fourth of all those admitted to the asylums are found to have suicidal tendencies. Lunacy is increasing more in the country than in the cities. In Hereford and Exeter there is a higher percentage than in London, yet the average increase of insanity in the capital has attained the enormous figure of 500. Dr. E. W. White, who was recently elected President of the Medical-Psychological Association, points out that not only is insanity increasing, but that in the last thirty years there has been no material advance in the rate of recovery, despite the numerous new and rational principles of treatment. London particularly suffers from unlimited numbers of the worst kinds of cases of aliens and needy town dwellers, whose poor bodies and poorer minds are often sapped by disease. For this and another great cause of the increase of insanity, namely, the marriages of those tainted with lunacy, Dr. White advocates State regulations. He is also in favor of such Government control for the mitigation of the chief cause of insanity, drink. England within the last fifty years has become a spirit drinking nation. There is no standard of purity for spirits, and it is probable that the badness and rawness of many cheap whiskeys is responsible for much insanity, which laws for enforcing purity and maturity of all alcoholic drinks would prevent. Another factor in the increase of lunacy pointed out by Dr. White is the strain of modern education, which accounts partly for the enormous increase in insanity in the last few years in patients of the middle and upper classes between the ages of 18 and 28. Another cause is the fact that late marriages in the upper classes and early marriages in the lower classes are far more common than they were fifty years ago. Either extreme in marriage is regarded by the doctor as bad for future generations.

**Two Physicians Drowned.**—Dr. Adolph Cudell and Dr. Ernest H. Leute, two prominent young Cleveland physicians, were drowned in Lake Erie, off the German-American Clubhouse, August 5th. The two young men had procured a boat and, rowing a short distance into the lake, entered the water. Suddenly one of them was seen to throw up his hands, while the other man was swimming toward him. Before aid from the shore could be given, however, both had disappeared. It is presumed that one of the men was seized with cramps and that both were drowned while the second man was trying to effect a rescue.

## CORRESPONDENCE.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

London, July 18.

THE KING'S SANATORIUM AND HIS ADVISORY COMMITTEE —SIR JAMES CRICHTON-BROWNE AS THE AVENGER OF CARLYLE—A SNUB FOR THE ANTIVIVISECTIONISTS—A VICTIM OF SCIENTIFIC RESEARCH.

I announced in my last letter that Sir Frederick Treves had retired from practice. This decision on the part of a surgeon in the very prime of life and in the full tide of success has naturally caused a good deal of surprise in the profession, mingled with speculation as to what a man so active proposed to do with himself during the long expectancy of life still before him. It has been publicly stated that he wishes to get into Parliament, but this soft impeachment he disowns. Whether this is more than an official denial remains to be seen. In the meantime the King consults him about all sorts of things. His Majesty has recently insisted on making him a member of the Advisory Committee to which he entrusted the building and organization of the Sanatorium which the calculated liberality of an Anglicised German Jew enabled him to found. The Committee has, I am told, incurred the wrath of the King because it has been so long incubating its plans. There was a difficulty in finding a site with a sufficient water supply; and now that a suitable site has been found there has been delay in getting to work. The King, who seems to think that sanatoria can spring up in a single night like mushrooms, is chafing at what he considers to be the dilatoriness of the Committee. Like the Grand Monarque who once said to his courtiers in horrified tones *J'ai failli attendre*, Edward the Seventh hates the very idea of having to wait for anything. He has added Sir Frederick Treves to the Committee in the hope that he may galvanize it into a more strenuous life.

The fact is that the King has conceived the notion that he has somehow been made the tool of designing persons in this matter. He expresses in racy Anglo-Saxon the belief that the movement for the suppression of tuberculosis is the crazy dream of a few faddists, which is being exploited by certain astute individuals for their own purposes, and he is furious at the thought that he has allowed himself to be used as a decoy. He thinks that the million dollars given him by Sir Ernest Cassel might have found a more useful application if the sum had been added to the King Edward the Seventh Hospital Fund. It is pretty clear that some interested person has got the royal ear and has instilled into it a poison which has had the effect of turning him against a scheme that might be of the greatest benefit to some of the most unfortunate of his subjects. He does well to be angry with his Advisory Committee, though not for the reason which he alleges. It is understood that it has signed a contract with a German physician who is to be the head of the new Sanatorium. This, when it becomes generally known, is certain to cause much indignation in the profession of this country. It was a fatuous thing to do, especially considering that two out of the six members of the Advisory Committee belong to the great Teutonic race. It is probably true that the nomination is due to female influence, to which our Gracious Sovereign is peculiarly susceptible, but, as is the way of royalty, he will doubtless throw all the responsibility of an unpopular appointment on the Committee. *Delirant reges, plectuntur Achivi*—the King rages, the Committee palavers, and poor consumptives suffer.

Sir James Crichton-Browne, who recently started an unsavory controversy about the married life of Thomas Carlyle, is one of the chief administrators of the Lunacy law, and can therefore speak with some authority on the vagaries of mad people. His judgment that poor Mrs. Carlyle at one period of her life suffered from insanity may therefore be accepted with the respect due to his special experience. But his attempt to represent Carlyle as a tender and considerate husband shows a talent for special pleading which might be regarded as incongruous in a scientific man were it not that men of science so often display such an amazing faculty of distorting facts and perverting the plain sense of words. Sir James Crichton-Browne, with a luxuriance of vituperation that would be more natural in a theological than in a medical controversialist, denounces James Anthony Froude for having traduced his hero. Yet Crichton-Browne's contributions to this controversy supply abundant examples of the un-

scrupulous methods with which he reproaches Froude. The general feeling in the profession, as far as I can gather, is one of disgust that a man who poses on platforms and in the newspapers as one of its leaders should have disinterred a forgotten scandal, and like one of the old "resurrection men" sold his foul booty for the delectation of the "many-headed beasts," which licks its chops with a special relish over any filth that seems to besmirch a great name. From most of the literary journals he has received very severe handling. But the thick hide of Scotch self-conceit in which he is swathed prevents even the keenest darts of criticism from penetrating to the quick. And his wares have doubtless sold sufficiently well for him to say with the miser in Horace:

Populus me sibilat, at mihi plaudo
Ipse domi, simul ac nummos contemplor in arca.

The Antivivisection cranks received a well-deserved snub from the Home Secretary the other day. No one can perform vivisection in this enlightened country without taking out a license like a publican or a cab-driver. It is the Home Secretary who grants these licenses; hence that functionary is freely used by the antivivisectionists as a target to shoot at. On July 15th a deputation from the Parliamentary Association of the British Union for the Abolition of Vivisection waited upon the Home Secretary and demanded that he should straightway suppress vivisection, or at any rate, until the time should arrive when public opinion would insist on its abolition, that he should lessen the number of experiments and the pain caused to the animals used for purposes of research. The Home Secretary, Mr. Akers-Douglas, dealt firmly and not over gently with the faddists. On one of them saying that the sight of vivisections induced a callousness that in some cases developed into a feeling of positive pleasure, the Minister declared that such a statement was a gross and grotesque libel on a high-minded and self-sacrificing profession. He went on to say that he had only to administer the Act (permitting vivisection under certain restrictions) and had no power to stop the practice. He declared further that nothing would induce him to introduce a bill for the abolition of vivisection into the House of Commons, or to recommend the Government to do so. The deputation had doubtless hoped to browbeat the Home Secretary, but got a lesson from him by which it is to be hoped that some of them will profit. The true inwardness of the situation does not appear in the newspaper reports of the interview. For two or three years past there has been internecine war between some of the leaders of the antivivisection movement—if that can be called a movement which never makes any headway. Miss Frances Power Cobbe and her adherents are abolitionists; their cry is *Delendum est laboratorium!* Mr. Stephen Coleridge on the other hand takes the more politic line of asking for the limitation of vivisection; he would not strangle it outright but slowly asphyxiate it by legal pressure. The two parties naturally hate each other with the fiercest sectarian hatred. The Coleridge faction has been a good deal before the public lately; it may therefore be surmised without much breach of charity that the deputation of the abolitionists to the Home Secretary was mainly inspired by the wish to show their supporters that they are still alive. There can be no doubt that antivivisectionism is losing ground in this country owing to the discreditable methods of controversy employed by its advocates. John Bull is stupid, but he likes common sense and he likes fair play; the wild denunciations of research offend the former sentiment, while the vile lies and odious imputations, thrown at scientific workers like filth in the hope that some of it may stick, outrage the latter. The followers, alike of Miss Cobbe and of Mr. Stephen Coleridge, are mainly composed of soft-hearted women and soft-headed men who greedily swallow any calumny, however gross, that may seem to discredit science which they hate with all the virulence of ignorance and prejudice.

In the list of pensions recently granted by the Prime Minister I see the name of "Mrs. Zare Elizabeth Blacker in recognition of the services of her late husband, Dr. A. Barry Blacker, who lost his life through his devotion to medical research, £120." This is the widow of Dr. Blacker, of whose sad fate I had something to say in a previous letter. He cured the King of a small rodent ulcer by the application of the X-rays, but himself fell a victim to an extensive malignant growth involving the shoulder joint. While curing the King he might have said, like the gladiators in the Roman Circus, *Ave Cæsar Imperator, Morituri te salutat!* The disease which killed him began in a burn of the hand caused by X-rays; this is probably the meaning of the allusion to his death having been caused by his devotion to medical research. The amount of money at the disposal of the Prime Minister for Civil List pensions is very limited; but I think some way might have been found of rewarding Dr. Blacker's important services more liberally than by a pension of $600 to his widow.

## THE HOMBURG SPA.

*To the Editor of the* Medical News:

Dear Sir: This representative German spa lies about 17 miles southeast of Frankfort-on-Main, from which city it is reached by frequent trains in from 25 to 32 minutes. The location is in the foot-hills of the Taunus range of mountains, about 600 feet above the sea-level. The town contains about 9,000 inhabitants and has been well known as a watering place since 1834. There are indubitable indications, however, that the early Romans who occupied the Taunus district from the beginning of the Christian Era until 300 A.D., used the water for medicinal purposes, as the foundations of their baths and sanatoria are still found in excavations for buildings, etc. There are documentary proofs of this use in the year 773. The situation here presents many natural advantages which the art of man has greatly extended and diversified. The town is situated on rising ground sloping from N.W. to S.E., and giving the main streets, three in number, the same direction. These are crossed at almost right angles by five or six side streets, running N.E. and S.W., with a gentle fall from the center street of about one per cent. The soil consists of slate, with a substratum of impermeable clay. To the excellent natural drainage gained by the conformation of the surface cemented pipes have been laid through most of the streets during the last ten years, and at this time the town is building a second system of pipes, so that the house and drain waters are entirely separated and all impurities carried out of the municipal precincts at once. The condition of the streets is positively unexceptionable from a sanitary point of view. It makes a New Yorker thoughtful to observe the jealous care with which minute scraps of paper, fallen leaves, etc., are gathered up and removed. The main streets are exceedingly attractive, being well-lined with shade trees and bordered by attractive and well-built hotels and private residences. Many of the latter indicating by modest signs that rooms are "Zu Vermiethen." Even Paris itself might be proud of the Kaiser-Frederick Promenade, the principal driveway facing the Kur-Park, and containing the villas of the wealthy summer residents.

The season here, as at almost all the German spas, lasts from May 1st to October 1st. As at Saratoga, however, August is the most important month, and the season is at this time just getting into full swing. A majority of the foreign visitors are English, but many Americans are seen, and the writer was delighted with a big photograph of the ever-popular junior Senator from the Empire State in a shop window this afternoon. The occasional torrid days at our home resorts are not known here. Light wraps are desirable toward evening all the summer. The temperature during the last few days has ranged from 55° to 68° F. The American visitor is struck by the entirely different management of the German spas from our own. Instead of being conducted by private individuals the springs are under the control of the town authorities. Our thrifty Teutonic friends have long since become acquainted with the value of their mineral springs as a source of revenue to the government. Every person remaining longer than three days in Homburg during the "season of cure," *i.e.*, from May 1st to October 31st, is looked upon as being here for the benefit to be derived from the waters, and therefore obliged to take a "Kur ticket" on the third day after arrival. The payment of the tax entitles the visitor to the use of the mineral waters for drinking, to the privilege of buying bath tickets, and gives admission to the Kur-gardens, promenades, concerts, etc. The tax for the season amounts to 20 marks ($4.80) for one person and somewhat lower rates for additional members of the same family. On the exempt list, I am happy to say, are physicians and surgeons and their families.

There is nothing hap-hazard about the treatment here. The first thing the health-seeker does after getting himself settled is to place himself absolutely in the hands of one of the medical men of the town, of whom there are some 18 or 20. I am constrained to believe that all matters pertaining to the "Kur" are conducted on a strictly honest basis. The local physicians are exceedingly jealous of the fair name of Homburg. If the patient can be benefited by a stay here he is given advice and treatment accordingly. If his case is unsuitable for the waters and climate, he is warned to get out without undue delay. It is regarded as highly desirable by the faculty to present an attractive morbidity and mortality table for comparison with numerous watchful and jealous competing spas not far away. The springs at Homburg are seven in number, known as the *Elizabeth-Brunnen, Kaise-Brunnen, Ludwigs-Brunnen, Louisen-Brunnen, Stahl-Brunnen, Landgrafen-Brunnen*, and *Sool-spruden Brunnen*, or Brine-well. The Stahl-Brunnen and Louisen-Brunnen are chalybeates. The others may be classified as muriated alkaline salines; all contain free carbonic acid, while several show sulphureted hydrogen in appreciable quantities. Following is an analysis of the Elizabeth spring, the most important of the group, by Prof. Fresenius:

ELIZABETH-BRUNNEN, HOMBURG MINERAL SPRINGS.

(Muriated alkaline saline.)

Estimated in parts per 1000.

| Solids. | Grains. |
|---|---|
| Sodium chloride | 9.86 |
| Potassium chloride | 0.34 |
| Lithium chloride | 0.02 |
| Ammonium chloride | 0.02 |
| Calcium chloride | 0.68 |
| Magnesium chloride | 0.72 |
| Magnesium iodide | Trace |
| Magnesium bromide | Marked Trace |
| Calcium sulphate | Marked Trace |
| Baryta | Trace |
| Strontia | Trace |
| Calcium bicarbonate | 2.17 |
| Magnesium bicarbonate | 0.04 |
| Iron bicarbonate (of oxide) | 0.09 |
| Manganese bicarbonate (of oxide) | Trace |
| Nickel and cobalt bicarbonate | Trace |
| Calcium phosphate | Trace |
| Silicic acid | Trace |
| Total solids | 13.98 |
| Carbonic acid entirely free | 1.95 |
| Temperature of spring (10.6° Celsius) | 51°F. |
| Sp. gravity of water | 1011 |

This total of something like 800 grains of solid matter per 115 gallons, about three-fourths of which is common salt, does not show a remarkable mineral water. We have within our own limits many springs of this class, some of them indeed far richer in mineral ingredients. Yet the Elizabeth-Brunnen gives character to a group of mineral waters which have become justly celebrated throughout the civilized world. This is for the reason that to an undoubtedly valuable and useful medicinal agent to start with, has been added a most excellent and thorough *system* of application. The Germans do not question the value of their mineral waters nor the skill and integrity of the medical men who direct the treatment at their spas. As a consequence the results attained are very gratifying. Persons suffering from old and obstinate cases of intestinal catarrh, for example, come to Homburg, surrender themselves to the doctor, observe a prudent régime, indulge moderately in the serene and harmless pleasures of the place, drink the waters—always under instructions—and return to their homes in four, six or eight weeks, restored to health. Such has been the history of Homburg as well as many other continental spas for many generations past. It is not to be wondered at that spa treatment occupies so high a plane in the opinion of the profession as well as of the laity. The diuretic, laxative, antacid and bracing effect of the Homburg waters cannot be fully accounted for by a study of the analysis of the springs. Artificial waters constructed in accordance with the analysis have failed to produce the same physiological effects upon the human system. Possibly the science of "physicalische chemie" may throw some new light on the process of dissociation in saline solutions and the formation of "ionen." Investigation in this direction, however, has hardly passed beyond the point of scratching the surface; while waiting for further light our hard-headed and practical Teutonic friends are going right on enjoying the advantages which Nature has given them and leaving for their savants the task of working out theories and explanations. Very truly yours,

JAMES K. CROOK, M.D.

*Homburg vor d Höhe, July 23, 1903.*

## SOCIETY PROCEEDINGS.

### STATE MEDICAL SOCIETY OF WISCONSIN.

*Fifty-seventh Annual Meeting. Held at Milwaukee, Wisconsin.*

The President, J. V. R. Lyman, M.D., of Eau Claire, Wis., in the Chair.

**Hemorrhage into the Cranial Cavity Following Injury of Skull.**—This paper was read by Dr. Charles H. Lemon. He laid emphasis on the importance of such lesions, due to the peculiar nature of the case. As a result of many experiments a remarkable resiliency of the skull has been demonstrated. The pathology of

cerebral lesions has often been misinterpreted. Those cases which are accompanied by a slow hemorrhage are the most interesting. All tissues undergoing trauma react alike, the peculiar conditions obtaining in the skull causing peculiar symptoms. Injury to the skull, causing unconsciousness, should be carefully watched. The following symptoms point to intracranial pressure: A tendency to sleep, vomiting, twitching of muscles, incontinence of urine and feces, inequality of pupils, loss of reflexes, stupor with or without remission. It is not necessary that fracture have grave or fatal results. In fact, fracture is sometimes a means of reducing pressure and many cases with fracture recover. Even venous sinuses can be torn without fatal results. When infection occurs it may be delayed and death result from pyemia rather than meningitis. In discussing treatment the author condemned depletion and the use of ice bags, etc.

**Retrodisplacement of the Uterus.**—This was the subject of Dr. G. A. Kletzsch. The generative organs are protected by heavy walls and strong fascia. The support of the uterus other than ligaments must not be forgotten. The perineum gives great support while the ligaments hold up the uterus but loosely. The peritoneal reflexion is also a factor. The uterus is not in a fixed position; but the cervix is more or less fixed, the fundus being rarely at rest. The uterus belongs in the true pelvis. Among the causes which disturb the position of the uterus are labor, miscarriage, faulty and too early use of forceps. All of these suggest the importance of prophylaxis. Regarding treatment, slight local operations and long continued local treatment will often prevent the necessity of radical operation. The Alexander operation is ideal for simple displacement without adhesion. Vaginal fixation distorts the position of the uterus, abdominal fixation is not perfect; but is found the best operation available.

Dr. F. Shimonek, in discussion, emphasized the distinction between retroversion and retroflexion, and advocated the use of pessaries in selected cases.

Dr. W. E. Fairfield criticised the use of tight binders and continued dorsal decubitus after parturition as tending to induce displacement of the subinvoluted uterus.

**Presidential Address.**—The president's address dealt with the early history of the society and its present relationship to the American Medical Association. The territorial society recognized the County Society as a unit thus foreshadowing the theory now advocated by the national body. The author quoted freely from Dr. George H. Simmons' writings on reorganization of the profession and urged that the Wisconsin Society fall in line with the work done in many other States.

**The Scientific and Practical Value of Bacteriological Examinations of the Blood During Life.**—This was the theme of Dr. L. Hektoen, Professor of Pathology in Rush Medical College, Chicago. There has been much progress of late in the bacteriological examination of the blood. The proper method is by puncture of a vein at the bend of the elbow under strictest asepsis. Pain is insignificant and there is no danger.

In septic diseases very interesting cultures may be made, and the difference between local infection and general invasion of the blood may be demonstrated. Infection may occur with or without local lesions. This method has a special value with reference to treatment of specific serums. In all cases accurate diagnosis on an etiological basis is absolutely necessary. The bacteriological examinations aid us in prognosis. We find streptococcic cases frequently recovering. Ten per cent. of scarlet fever cases have been found to have the streptococcus in the blood. In pneumonia out of 100 cases, 95 showed the pneumococcus. The prognostic value of such examination is slight. In typhoid fever the typhoid bacillus is found in the blood from the beginning, and reappears with exacerbations. Blood examination is valuable for prognosis, particularly in the presence of epidemics. The typhoid bacillus was found in the blood of three cases of scarlet fever only one of which desquamated. Intestinal lesions of typhoid have no relation to the severity of the attack. The early pharyngeal point of invasion is through the medium of the tonsils. The paratyphoid bacillus has been found on the feet of flies. Many cases in the Ithaca epidemic gave negative results with the Widal test.

**Management of the Mother During Child-bed Period.**—This was Dr. A. D. Gibson's paper. He said raw surfaces of the uterus and genital tract are easy sources for infection. Complete involution of the uterus does not occur for three months and the woman should conduct herself with this in mind. Afterpains are more pronounced if the uterus has been excessively dilated, as by excessive amniotic fluids, etc. The writer opposes the use of the binder as tending to promote retroversion, opposes rupture of the membranes, frequent examinations and the use of douches, regarding the practice of ordering the nurse to give them as little short of criminal. A chill soon after labor is frequent and usually unimportant. The kidneys should be kept active and the lying-in room cool, cooler than is suitable for the child and the best plan is to have separate rooms for mother and child. As to diet, avoid slops. The child should be nursed at once. The bowels should be moved from twenty-four to thirty-six hours after labor with castor-oil or compound licorice powder.

**Shortcomings of the Physician, Particularly in his Relation to the State and Hygiene,** by Dr. Albert F. Fuchs. This paper dealt with the relation of the physician to the community at large with reference to other matters than those directly connected with medicine. The physician's attitude on questions of religion, politics and social questions are of greatest importance and there is much to be desired in the attitude of the profession toward these questions.

**Annual Address in Medicine. The Diagnosis and Treatment of Nephritis,** by Dr. Arthur R. Edwards. Among many other interesting things he said systematic and repeated examinations of the twenty-four-hour specimen of urine should make diagnosis easy; but there are exceptions. The total amount of urine may be decreased in the latter stages of nephritis or in the presence of hypertrophy. Albumin may be absent in individual cases or may be present in excess. Nephritis without albuminuria undoubtedly exists. Casts may be found at intervals when albumin is temporarily or permanently absent. Casts should be searched for even in the absence of albumin. Hyaline casts are found in normal urine; granular and epithelial casts signify degenerative or inflammatory lesions. Casts frequently follow operations and are found in toxemia. Parenchymatous nephritis may have no cardiovascular complications; but dilation or atrophy of the heart may exist. The heart may lead to or follow renal disease or both may be referred to a common cause. Edema in chronic nephritis is often due to permeability of the blood vessels. It is hard to say why some cases are so much more marked than others. Diagnosis of latent atypical non-albuminuric nephritis is especially important if other lesions are present. We must always think of all other possible diseases, and we can often only suspect the presence of kidney complications. Frequently the smaller the urinary the greater the pathological findings at the autopsy. Nephritis has

been found in twenty-five per cent. of autopsies where the kidney lesions had no particular significance during life.

Among the symptoms of chronic nephritis are those of the nervous system, digestive system, failure of the heart, complicating pneumonia, pleurisy, etc. When uremia is present, be sure that other possibilities are excluded. The pulse is important, being slow until complications are imminent, such cases may closely simulate digitalis poisoning. Uremia may simulate almost any brain lesion.

Preventive therapy is of importance, rest and exercise being fundamental. Rest in the horizontal position is good for kidney lesions. Passive exercise is useful if the heart is weak. When improvement occurs vigilance should not be relaxed. Rest in bed protects the skin and relieves vascular tension, and rest should be continued often for a year or more. Physical rest is of prime importance; after mental fatigue violent exercise should be avoided. The diet should be non-irritating;—limit albuminous foods; give fats and carbohydrates freely. Avoid albuminous foods because they must be eliminated by the tubules. Do not diet too much on general principles, if the patient loses weight the diet should be altered. Few patients cannot take milk, if it is taken as food and not as a beverage. Avoid tea, alcohol, coffee and spices. For the edema, diuretics are recommended; but are unsatisfactory. Do not allow catharsis to interfere with the weight. Sweating eliminates fluids rather than solids; causes too much concentration of the blood, and favors uremia. Mechanical removal of fluids is better, a deep incision (3 inches long) in the leg will often bring from one to three gallons of fluid containing .2 per cent. of urea. This urea is thus removed from the circulation directly. In the last stages the heart is the main feature. Avoid irritation and overstimulation. Hypertrophy is a favorable condition; but it only postpones the fatal issue.

**Indigestion; A Few of its Causes and Effects.**—This paper was read by Dr. H. B. Sears. He said any break in the complex chain of digestion ruins the whole. Environment plays a large rôle. Early detection of indigestion is of great importance. Too many members of families, varying in age, eat the same kind of food without discrimination. Haste in eating is the most fruitful cause of indigestion; poor teeth are scarcely less to blame. Insufficient cooking is the bane of the American stomach; for instance, beans should be boiled ten hours and then baked five hours in the oven, a process which it is hard to induce American cooks to agree to. Children under ten years of age are better without meat. All cases of indigestion should be treated individually and no general rules can be laid down.

**Semilunar Cartilages, Their Anatomy and Surgery.**—Read by Dr. H. A. Sifton. This paper dealt with the anatomy of semilunar cartilages; and various forms of displacement which may occur and the treatment both operative and otherwise. The importance of rest was emphasized and the use of passive motion; and especially the necessity for restricted motion for a long period.

**Sequelæ of Adenoids.**—This was the subject of Dr. C. D. Conkey. He said that adenoid growths are a disease of childhood and generally pass away with adolescence; but the effects remain. Deformities of the nose and even of the jaw may result from neglected and excessive adenoid growths. There may be arrested development of the bones of the face. The chief trouble comes from prolonged mouth breathing which at once disappears after the growths have shrunk. Hypertrophic catarrh, affections of the ear, tonsils and often larynx and bronchial tubes are some of the unfortunate and often permanent results of a comparatively insignificant affection.

**Significance of the Perforating Wounds of the Eyeball.**—Read by Dr. J. A. Bach. Aside from the direct results of injury to the eyeball, which are to be treated on ordinary surgical principles, our chief care should be directed toward the avoidance of sympathetic ophthalmia. The old theory, which has been largely discarded, is again coming into quite general acceptance, namely, that sympathetic ophthalmia may develop without infection. Ciliary reflex plays a large rôle in the development of sympathetic ophthalmia and our chief care should be to avoid all possible sources of irritation.

**Diagnosis of Hysteria.**—Read by Dr. Hugh T. Patrick. This paper dealt with cases of hysterical anesthesia following trauma. Our chief diagnostic point in distinguishing hysterical anesthesia lies in the fact that the line of demarkation is so sharply defined and fluctuating, being found to vary on repeated examinations. Great care should be exercised to detect the presence of other diseases coexisting with hysteria.

**Prostatectomy.**—This paper was read by Dr. T. W. Nuzum. He summed up as follows: (1) Prostatectomy is an operation destined to give great comfort to patients suffering extreme pain; (2) the perineal route is the best; (3) the operation is warranted even in advanced old age; (4) weeks should be given in preparation before the operation; (5) the horseshoe incision is the best; (6) the greatest danger lies in hemorrhages, especially if due to sclerotic arteries; (7) the results are encouraging considering the bad conditions under which such operations are generally done; (8) better technic will bring better results.

**Post-mortem Degeneration of the Pancreas.**—Paper read by Dr. Wm. F. Becker. He advanced the theory that microscopical examination of the pancreas may under some conditions give decisive evidence as to the length of time which has elapsed since death has occurred and may prove of value in medicolegal questions. The pancreas is a valuable organ for such examination, owing to its comparative freedom from disease and its protected situation in the abdominal cavity. Many factors must be considered in drawing conclusions from the post-mortem appearance of the pancreas, such as temperature surroundings following death, length of time after the ingestion of food, etc. In support of his theory numerous microphotographs showing the pancreas at varying intervals after death demonstrated the different way in which degenerative processes occur in the different histological structures of the gland.

**Albuminuria in the Apparently Healthy.**—This was the subject of Dr. W. H. Washburn. He reported the histories of 258 cases of albuminuria discovered in supposedly healthy persons applying for life insurance examination. Thirty-five of this number showed evidences of disease such as cardiac murmurs, casts, cystitis, etc.; eleven of these cases are dead from unknown causes, 70 have been lost sight of. Out of the 153 remaining cases 6 have died, 2 from pulmonary tuberculosis, 1 from pneumonia, 1 from paralysis, 1 from acute Bright's disease and 1 without a diagnosis having been made. The mortality among these cases, if we make allowance for the 35 mentioned, is smaller than would have been expected. Out of 100 cases due to albuminuria only 14 still show albumin. The evidence shows that the treatment instituted appeared to be very beneficial. No one line of treatment, however, was pursued in all these cases.

**Annual Address in Surgery.**—This was delivered by Dr. William J. Mayo, of Rochester, Minn. The

author presented conclusions drawn from a study of 900 cases of operations in the upper abdominal cavity. There is a close relation between the affections of the gall-bladder, bile passages, stomach and duodenum. The duodenum acts as a sort of buffer and is secondarily attacked: the same is true of the pancreas. Abdominal surgery owes much to pelvic surgery. Mistakes there have helped us later in gastro-enteric work. Surgery of the stomach has had to live down a bad name. The stomach is one of the most favorable organs for operation, and the chief difficulty lies in the diagnosis. Ignorance breeds complexity and at least half of our stomach diseases must go. The author states that out of 1,100 cases, where careful examination was made of the stomach contents and the position of the organ, 300 were operated and the diagnosis found correct in 80 per cent. Chemical examination of the stomach contents is often negative and should not be too greatly relied on or cause us to delay too long before operating. Exploratory incision is indicated in all doubtful cases. To get an outline of the stomach, a stomach tube and ordinary Davidson syringe are sufficient. Refinements of technic are found harmful. Simple methods give enough to warrant sending the patient to the surgeon for treatment.

**Ulcer.**—Do not confuse acute and chronic symptoms, pains exist chiefly in old ulcers only; the nearer the pylorus the greater the pain. Ulcers of the duodenum give symptoms resembling those of gall-stones. Pain may disappear for some time and hemorrhage and vomiting are rare and late. Cure may result from rest, but the ulcer may return. Out of 500 cases in a London hospital, 211 had previous attacks, 18 per cent. died, 42 per cent. are doubtful cures, most of these cases are surgical. Ulcer is often diagnosed as cancer. Chronic ulcer is a disease of adult life. Drainage operation gives marvelous results. Two hundred cases show the ulcer mostly to the right of the pylorus on the great curvature, then there is great pain from pyloric spasms. Surgical treatment is not settled. Excision of the ulcer is found feasible, but it is often hard to find. Redmond has suggested excision of the pylorus, the so-called "ulcer-bearing area." Dilation without organic trouble, where there is no retention and little stagnation, is not much benefited by operation; this is true also of gastroptosis. Beware of neurasthenic stomach.

**Cancer of the Stomach.**—Early diagnosis and operation are very necessary. In five years operations for cancer of the stomach will give as valuable results as are obtained in cancer in the breast. Return of the disease is more often found in the liver than in the stomach on account of the blood and lymph supply.

**Ethyl Chloride as a General Anesthetic.**—This was Dr. Franz Pfister's paper. He said that only pure ethyl chloride must be used; no methyl chloride must be present. The preparation called kelene has been found to be reliable. Failure and accidents have been due to impure drugs and faulty administration, the results are good, as there is an absence of unpleasant by-effects. The use of ethyl chloride is limited to minor surgery. Patients should be prepared as for other forms of anesthesia, a cone may be used as for nitrous oxide, tight over the face or it may be sprayed on a double layer of gauze. From 5 to 20 c.c. will produce anesthesia for ninety seconds. Anesthesia may be maintained from six to ten minutes; pupillary and conjunctival reflexes are all that need to be watched; dilation of the pupil is a danger signal; breathing is slightly stertorous. Previous hypodermatic injections of morphine are recommended.

Dr. Thienhaus, in the discussion, stated that Kocher has rejected the use of ethyl chloride and reports 7 deaths in 17,000 cases.

**Diagnosis and Treatment of Some of the Inflammatory Conditions of the External Ear.**—Read by Dr. Gilbert E. Seaman, who said that catarrhal inflammation of the external ear is a misnomer, as there is no mucous membrane in the external ear. Furunculosis should be treated early, and is a very painful and troublesome affection; the nearer the tympanum the greater the pain. Recurrence is very frequent. Treatment on ordinary aseptic lines; incision under local anesthesia and the use of a 50-per-cent. solution of argyrol. Eczema is very difficult to treat, care should be given to hygiene, diet, use of laxatives, avoidance of soap and water and thorough removal of crusts, débris, etc. Spray with peroxide of hydrogen, or yellow oxide of mercury 2 gr. to the ounce, as also oil of ergot.

**Septal Deflections.**—This interesting paper was read by Dr. F. T. Nye, who said that septal deflections may be classified (1) as simple, (2) deflections with excess of tissue, (3) deflections with slight or partial excess. Etiologically they may be classified as due to congenital malformations or traumatism. As a result we have imperfect respiration, pharyngeal and laryngeal, and imperfect drainage from accessory sinuses. Both speech and smell may be affected. The treatment is chiefly surgical. The floor of the nose must be depressed, redundant tissue must be removed, the septum must be readjusted and maintained in position. Cocaine and adrenalin solution are indispensable. The writer prefers a blunt punch for operations on the septum, sterile gauze may be used for the first twenty-four hours, followed by a splint.

**The Practice of Obstetrics.**—This was the title of Dr. E. F. Fish's paper, who said the importance of strict asepsis and careful after-attention cannot be too greatly emphasized. Too much obstetrical work is left for the younger and inexperienced physician, older physicians avoiding this class of work partly on account of inadequate compensation. Examinations should be as infrequent as possible, douches should be avoided and the case be considered as strictly surgical.

This paper was very elaborately and thoroughly discussed by Dr. Scollard and others, and in the matter of examination and the position by outside manipulation many differences of opinion were brought forth.

**The Depurative Functions of Organs.**—Read by Dr. C. R. Brown, who remarked that all life is at first referable to a single cell. Differentiation arises first as a sort of inflammatory reaction, it is Nature's response to outside insults. Inflammation is only a natural process exaggerated. The location of inflammation is of great importance. Edema of the hand is quite a different thing from edema of the glottis; inflammation of the finger is a different thing from inflammation of the appendix. The lungs, liver, etc., have functions other than the conventional ones of the organs, these are of a depurative nature, for instance, the liver is well known as an important agent for the arrest of poisons. The lymph system also plays an important part, and this is true of the ductless glands. Tonsillitis is not due to a specific microbe; many bacteria can cause tonsillitis, and disease is often arrested by the tonsils with resulting inflammation of these organs and no further bodily invasion. The Klebs-Löffler bacillus may cause merely a simple tonsillitis and the general system escape diphtheria. The author reported and analyzed several interesting cases.

**Myomectomy of Uterine Fibroids.**—This paper was read by Dr. A. J. Puls, who said that myomectomy is recommended in younger patients who have not reached the menopause. It is in accord with the general principle that all healthy tissue should be left, it is particularly recommended for fibroids because return of

the disease is not common, and not so grave as in the case of malignant disease.

**Surgical Progress.**—By Dr. W. H. Earles. The author reviewed the progress of surgery during the past year, calling attention to the notable progress being made in gastro-intestinal work, prostatectomy, etc.

**Manifestations of Rheumatism in Infancy and Early Childhood.**—This most interesting subject was introduced by Dr. Arthur T. Holbrook, who said that great confusion in terms and much progress is needed in accurate diagnosis. The cause of rheumatism is an accumulation in the blood of something which irritates; especially irritating to the synovial membranes. Both the uric acid and the lactic acid theories have been refuted, and we are still in the dark. Acute articular rheumatism is rare under three years of age, the cases of grip, etc., are often misnamed rheumatism. Temperature in children with rheumatism does not often run high. Joint swellings are slight and not many joints are affected at once. Heart involvement is so common as almost to be a symptom rather than a complication. Eighty-three per cent. of cases under ten years have heart symptoms. Peculiar heart sounds often accompany involvement of that organ; there is a sort of dulness or muffling, a "murmurish" sound. Subcutaneous fibrous nodules are often found about the joints and tendons in children. Diagnostic points are heredity, history of previous attacks, and general clinical picture; exclude the following: multiple neuritis, tuberculosis, syphilis, scurvy and "growing-pains." The danger in rheumatism comes almost always from the heart.

**New Officers.**—The following officers were elected: President, Dr. F. E. Walbridge, Milwaukee, Wis.; First Vice-President, Dr. James Mills, Janesville, Wis.; Second Vice-President, Dr. C. C. Galiot, Shullsburg, Wis.; Secretary, Dr. C. S. Sheldon, Madison, Wis.; Treasurer, Dr. S. S. Hall, Ripon, Wis.; Delegate to the American Medical Association, Dr. Evans, La Crosse, Wis.

The Society adopted the constitution and by-laws recommended by the American Medical Association, thus following in line with the majority of the States of the union. Seventy-eight members were added to the membership of the Society, and it is expected that during the coming year County Societies will be organized throughout the State. A committee of ten was appointed to serve as temporary council until organization throughout the County shall have been completed.

---

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Regular Monthly Meeting, held June 3, 1903.*

The President, Charles N. Dowd, M.D., in the Chair.

The scientific business of the evening consisted of the reading by Professor Ewald, of Berlin, of a paper with the title On Stomach and Intestinal Crises.

**Abdominal Pains.**—Professor Ewald said that there are many causes of pain in the upper abdominal region that must not necessarily be referred either to the stomach or the intestines. Renal colic is not infrequently localized in the upper part of the abdomen and is not always referred to the part or the kidney affected. It has often been noted that renal calculi when forming are apt to give a sense of acute discomfort in the upper part of the abdomen on either side. Gall-stones in process of formation give rise to pain of the same kind, which not infrequently is localized in the right epigastrium as if it were the result of stomach or duodenal conditions. Pancreatic calculi are usually rarer and the pain is commonly referred to the other side, but the possibility of their occurrence must not be forgotten or serious mistakes may be made, especially as pancreatic operations are indicated as early in the case as possible, and physicians should recognize them before complications have occurred, if possible.

**Stomach Pains.**—There are many causes of pain in the stomach itself besides the gastric crises which are referred to degeneration of the sensory tracts of the cord. Ulcer of the stomach may give rise to severe pains of burning character, though the differential diagnosis is usually not difficult if the physician secures a good history of the case or finds a point of localized tenderness in the abdomen just over the region of the ulcer. True stomach pain may also be due to spasm of the pylorus. This is not frequent, but its occasional occurrence can scarcely be denied. This type of pain is a true colic, being due to a spasmodic contraction of a mucous-lined canal. Intestinal worms may at times give rise to painful conditions referred to the stomach or duodenum, probably consequent upon the wandering of the parasite into the upper part of the intestinal tract.

**True Gastric Crises.**—One of the most interesting forms of pain in the upper abdomen is due to the occurrence of stomach crises in what is known as locomotor ataxia or tabes dorsalis. These cases have only been recognized in their true character in comparatively recent years, but they form at the present time an important part of the work of the specialists in diseases of the stomach. In the last ten years Professor Ewald has seen 89 cases of the affection, but he has the notes in detail of only about 50 of the cases. These details are, however, sufficient to give a very good idea of the frequency of the affection, of its probable etiology, of its peculiar symptoms and course, and of the treatment that has sometimes been found effective.

**Syphilis as Cause.**—The first question that naturally arises is how frequently can syphilis be found in the history of these cases. Out of the 50 cases, 26 either confessed to syphilis or showed traces of syphilitic lesions. This is about 60 per cent. of the number, and this percentage is about what has been found by neurologists in the history of tabes generally. In some of the cases the primary and secondary lesions of syphilis were more than ten years past. Usually a number of years had gone by since the last signs of any syphilitic lesion had been seen. Not infrequently the gastric pain was the first symptom of the beginning of tabes dorsalis. Sometimes other symptoms, especially those in the eyes or in the station, the so-called Romberg symptom could be found on careful examination, though the patient had known nothing of their existence before the attack of pain.

**Duration of the Disease.**—In some of the patients under Professor Ewald's care the gastric crises continued for more than ten years. The average length of the cases is about three years. One patient had his first attack of tabes only two months before he came under observation. The attacks recur at intervals. At first these intervals are long, sometimes there is no recurrence for over a year or even two years. Then the intervals become shorter until finally the gastric crisis is repeated every week or two. The attack of pain lasts from one-half hour to forty-eight hours. Very few cases get any relief for at least several hours after the beginning of the attack. The pain is localized in the epigastrium and the preliminary sign of the attack is a causeless nausea followed by vomiting. The vomit consists at first of food and then mucus, followed by blood in streaks. Twice Professor Ewald has seen the vomiting of blood accompanied by melena. This is rare, however, and is probably due to the rup-

ture of small blood-vessels during the efforts at vomiting.

**Character of the Attack.**—The pain usually comes on very suddenly and is described by the patient as lightning-like in character. At times, however, there is some warning of it in a sense of discomfort. This is a sort of aura in the chest and back. Gradually then the pain becomes worse until finally it takes on the cramp-like character of a true colic. There is usually a feeling of intense constriction around the waist. Vertigo occasionally accompanies the affection. Once Professor Ewald saw a true fainting spell that lasted for some time and seemed to have no other cause besides the irritation of the gastric nerve endings.

**Pre-ataxic Symptoms.**—Not infrequently these gastric symptoms occur for a long time before any characteristic ataxic symptoms can be discovered. There may be absolutely no difficulty of locomotion or station. In one of Professor Ewald's cases five years passed before the other symptoms of tabes became noticeable. In several cases more than a year of absolute freedom from any other tabetic symptoms was noted. The gastric pain is not accompanied by any definite invariable pathological change in the stomach contents. The most frequent change noted was a certain amount of subacidity. This seems to be due to a lowering of the activity of stomach functions generally. In the interval between the attacks the stomach contents show no signs of the condition. Usually the patient is quite comfortable as regards his gastric function, but at times there is a continuous dyspepsia of nervous character and likely to have anomalous symptoms. The diagnosis of the condition then must be made rather from the sudden and lightning-like attacks of the pain and the associated symptoms than from any information that can be obtained from the stomach.

**Rectal and Anal Crises.**—Intestinal crises are ever so much rarer than stomach crises. They occur usually in the rectum and anus. Intestinal crises of any kind are accompanied by board-like hardness of the abdomen, due to a tense contraction of the abdominal muscles occasionally with protuberances of parts of the wall because of spasm of the intestines situated directly below. Not infrequently gurgling sounds may be heard and after these the protuberances disappear. Usually these phenomena are followed by an intestinal movement and, as a rule, do not last long. Anal crises are accompanied by intense desire to go to stool which cannot be satisfied. Patients describe their sensations as being excruciatingly painful, as if a hot iron were being pushed up their rectum. Commonly these do not last long and then the patient is as well as ever. As with regard to gastric crises, the intervals between the attacks are likely to become shorter and the patients suffer obstinately and without much hope of relief until the further degeneration of nerve tracts destroys the sensory paths.

**Diagnosis of Gastric Crises.**—The diagnosis depends upon two elements, the previous history and the tearing, lightning-like character of the pain. When the attack occurs for the first time, diagnosis is extremely difficult. There is likely to be the thought of some serious intestinal condition, as obstruction or some intensely acute gastritis. Frequently when the vomiting is continued during the course of an attack it is difficult to separate it from functional nervous vomiting. There is a condition of periodic vomiting entirely neurotic in character, which occurs and may simulate a gastric crisis. Idiopathic vomiting as described by Leyden, that is recurrent attacks of vomiting without any gastric pathological conditions and without any nervous involvement must also be differentiated. This condition is not very frequent, however, and the attacks are neither so violent nor so sudden in their onset and the patients are usually of neurotic family and personal antecedents.

The pernicious vomiting of pregnancy is, of course, well known and, as a rule does not require very careful differentiation from tabetic crises. It must not be forgotten, however, that women suffering from the beginning of tabes may become pregnant and that vomiting during pregnancy therefore does not always mean reflex vomiting from uterine stimuli. Stone in the kidney or biliary passages may give rise to distinct spasms of pain accompanied by vomiting. These may be recurrent in character and thus give rise to the suspicion of tabes. Serious mistakes may be made in this matter, especially as surgical intervention in biliary and other conditions should be undertaken early to be successful and the stomach specialist is expected not to allow the diagnosis to remain undecided too long.

**Mistakes of Diagnosis.**—There are a number of reported cases in the literature in which gastric crises were mistaken for other conditions, to the serious detriment of the patient. Werner reported a case in 1883 which, owing to the existence of pregnancy, was considered to be reflex vomiting, but after the uterus had been emptied the cervix thoroughly dilated and the interior cauterized, the attacks continued to recur. The painful seizures were then considered to be due to spasm of the pylorus and the attacks were supposed to be due to attempts of the stomach to pass along its contents through the contracted pyloric orifice. Accordingly a gastro-enterostomy was advised and after some delay was performed. Absolutely no effect was produced and the attacks continued to recur. The old theory that the condition was due to reflexes from the uterus was then taken up again and the patient's uterus and ovaries were removed. This procedure was also without good effect. Three years later the patient developed other signs of tabes and it became evident that the whole set of symptoms had been due to the degeneration of the cord and associated neurons.

**Causes of Gastric Crises.**—The true nature of the tabetic crises is as yet in the dark. It has been supposed that the degenerative process caused by the sclerotic condition affects the nucleus of the vagus and the ganglia associated with it. After complete degeneration has taken place the attacks cease and it is usually true that as the tabes progresses the attacks become less frequent and less bothersome and finally disappear entirely. This theory would not explain the gastric crises which precede all the other signs of tabes. For these the theory has been suggested that there is an irritant toxin in the blood of patients who have suffered from syphilis and that this causes an irritative degeneration of nerve substance with consequent production of attacks of pain in sensory nerves and vomiting because of the effect on the vagus which is connected reflexly with these and is distributed to all parts of the stomach.

**Treatment.**—Unfortunately with all our knowledge of the affection there is very little that can be done for the patients either during an attack or in the interval between attacks. There is no known means of surely shortening an attack. Various coal-tar products, especially antipyrin have given good results in certain hands, but have proved of no service to others at all. Morphine sometimes does good, but sometimes fails utterly to give relief. Where vomiting is a prominent symptom and more annoying than the pain, cerium oxalate has been known to do good, though in Professor Ewald's hands it has not proved of very great benefit. In the intervals between attacks strychnine has been recommended and, according to conservative observers, has been known to lengthen the time be-

tween attacks and to make succeeding attacks less severe than those that have preceded the administration of this treatment. It is evident that suggestion plays an important rôle in the treatment of the condition, since each new method that is invented does some good in the hands of the physician who originally suggests it. Morphine remains the drug to be depended on, but it must be increased very much in successive attacks in order to have a satisfactory effect. Professor Ewald has seen cases in which large amounts of morphine were employed with only a modicum of satisfaction. One-third to one-half grain of the drug may be given repeatedly at short intervals and only produce slight alleviation of the symptoms.

**Spinal Anesthesia.**—Dr. Corning suggested some years ago the use of injections of dilute solutions of cocaine into the spinal cord with the idea of producing spinal anesthesia. This suggestion was taken up by French surgeons and has now been employed sufficiently often to make it clear that there is very little danger associated with it. In the hands of certain observers this method has done more to relieve the pains of gastric and intestinal crises than any other. Where the crises recur frequently and where all the ordinary drugs fail to give much relief, this method of treatment should certainly be employed. Nothing is more discouraging than to see the remedies so often recommended fail one after another to give relief in the intense tearing pains which accompany gastric and intestinal crises. As closely related to intestinal and gastric crises, Professor Ewald considers that the tearing pains which sometimes affect the bladder in the course of tabes should also be mentioned. As in the corresponding anal crises, there is apt to be an intense desire to empty the viscus, which cannot be satisfied and the patient describes his feelings as being so excruciatingly painful that there is the impression of a red hot iron being forced through the urethra into the bladder. These are even more obstinate to treatment than are the intestinal crises and the method of spinal anesthesia seems specially indicated. Ordinary anodynes often fail entirely to have any effect and patients live in constant dread of the return of the awful pain. This is of itself sufficient to make their condition more miserable than it would otherwise be and probably also to shorten the intervals so that the physician should not hesitate to employ so apparently serious a remedy.

**Idiopathic Crises.**—There are a certain number of attacks of intense pain that occur in the abdominal region referred to the stomach or intestines or to the bladder that simulate the crises of locomotor ataxia yet have no connection with the disease. At least none of the characteristic signs of true tabes ever develop to make the diagnosis assured. These cases often yield to treatment by tonics, or by high irrigation. Needless to say in all cases ordinary methods of treatment by irrigation, washing out the stomach and the rectum and large intestine and also the bladder, must be tried before recourse is had to large doses of anodynes, or to the method by spinal anesthesia.

**American Universities and Hospitals.**—Professor Tillmanns, the distinguished German surgeon was then introduced and said that his visit to America had proved to him what magnificent work was being done in the universities and hospitals of this country. He feels that he is leaving the American shores a better surgeon than when he came. German students of medicine will have to come more and more to this country if they want to appreciate the progress that is being made by an enterprising people in the practical sciences and especially in the department of surgery. The hospitals of this country particularly are worthy of all praise and are models for the world. Professor Tillmanns considers that he will always look back with the greatest pleasure on his visit to America and that he will feel the necessity for coming back again ere long in order not to miss any of the good work that is being done here.

**Germany and American Medicine.**—Dr. D. B. St. John Roosa said that in the early colonial days American medicine received its encouragement and the aid in scientific matters from Amsterdam. The first physicians who came to New York were pupils of the school of Boerhaave, of Leyden. After this the main influence in medicine came from Edinburgh. Munro's and Syme's influence were deeply felt by New York physicians and surgeons and as the country improved more and more physicians were enabled to go to study under their special care. Later France took the place of alma mater for American medical students and held it for many years. At the end of the first quarter of the century Laennec and a little later Nélaton and Trousseau were the masters in medicine to whom American medical students owed very much. It was only in the last quarter of the nineteenth century that Germans and German medical methods came to have the influence now so prominent in American medical matters. Roosa himself was one of the first to go to Germany before going to France for medical studies. On his return he translated several German works on the eye and ear into English. After 1870 German medical works began to be translated into English and it was not long before Virchow and others were the names most familiar to American medical students.

---

## THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting held at the New York Academy of Medicine, June 8, 1903.*

Ransford E. Van Gieson, M.D., in the Chair.

**Anesthetics.**—The first paper of the evening was by Dr. Edward Wallace Lee, on this subject. Speaking of spinal cocainization, he said that his experience with this method was limited to 15 cases, 12 of which were surgical and three obstetrical. In the latter it was not at all satisfactory, the injection apparently losing its anesthetic effect just at the time required, while the patients suffered from its unpleasant effects, nausea and extreme nervousness. In the surgical cases there was one abdominal section for tubo-ovarian abscess. The incision was made without the least distress to the patient, but when he inserted his fingers into the abdominal cavity she grew restless and highly hysterical. A loop of intestine presented itself in the wound, which, unfortunately, the patient saw. She became maniacal, and it was necessary to complete the operation under chloroform narcosis. In the other cases the results were fairly satisfactory, but not sufficiently brilliant to cause him to resort to spinal cocainization when any other form of anesthetic could be used with any degree of safety.

**Ethyl Chloride.**—For minor surgical procedures Dr. Lee has found this substance very satisfactory as a local anesthetic.

**Cocaine Local Anesthesia.**—The local and hypodermatic administration of cocaine he has found of very great service in innumerable instances. The following are the principal indications for its use: (1) A short operation; (2) no especially sensitive structures to be incised; (3) the ability to bring every part involved in the operation under the influence of the cocaine. (4) In patients whose condition of extreme exhaustion is such that the additional shock of a general anesthetic

would take away their only chance of life. When cocaine was first introduced he used it locally on mucous membranes, as in the nose, throat, mouth, vagina, rectum and penis, with good results as far as the anesthetic effect was concerned; but he soon discovered that he was employing it too freely and in too strong a solution, as it produced serious constitutional disturbances. Two cases were almost fatal, and these he described in detail. He has made several abdominal sections under the use of cocaine with gratifying results, and has employed the infiltration method in hernia and appendectomy. His most satisfactory results with cocaine as a local anesthetic have been on the extremities. Here he has made amputations, removed growths, curetted ulcers, ligated vessels, sutured wounds, etc. In his experience, if the extremity be elevated until gravity has quite blanched the member, and an Esmarch's bandage is then applied, local anesthesia has a wide range of usefulness and the patient does not suffer from such severe constitutional disturbances as when the cocaine is permitted to enter the general circulation.

**Suggestion and Deception.**—In a few instances Dr. Lee has been able to perform minor and superficial operations by assuring the patient that the part to be operated upon was not susceptible to pain; also by allowing the patient to believe that he was using a powerful local anesthetic, when nothing but sterile water or alcohol was employed. In a very few cases he has succeeded in placing a patient in a hypnotic state sufficient for a minor operation. One case in illustration of this was given.

**General Anesthesia.**—General anesthesia is to be performed in all cases where there is not some good and sufficient reason to contra-indicate its use. A feature of it which is one of its greatest advantages, but which is too little appreciated, is that blessed oblivion which envelops the patient throughout the operation. He has not been favorably impressed with the various combinations of ether and chloroform, preferring to use one or the other alone. Occasionally it may be advisable to discontinue the one and substitute the other, but even this does not seem to have many indications.

**Comparative Merits of Ether and Chloroform.**—So far as safety was concerned, Dr. Lee said he was well aware that ether has the preference. It is its reputation for this which has made it the popular anesthetic, especially here in the East. Personally he has never seen a death from chloroform, while he has had two deaths which could be directly attributed to ether. Ether certainly has many disagreeable features: length of time required; quantity used; struggling stage of excitement; irritating effect on the respiratory tract. Moreover, it is almost invariably followed by nausea and vomiting. Its effects last for several days, the patient complaining of smelling and tasting it. It is also highly inflammable, a factor which generally precludes its use in obstetrics. He considered ether more dangerous than chloroform in Bright's disease, diseases of the respiratory tract, and grave vascular diseases. As a result of his own personal observation, he was prejudiced in favor of chloroform. While serving in 1880 as assistant to Donald Maclean, then Professor of Surgery in the University of Michigan, he administered it about five hundred times, not meeting with any unfavorable complications which would alarm him or discourage him in its use, and since then he had continued to employ it. From his personal experience he could not look upon ether as the safer of the two. Of late, however, he had to confess that he had become more tolerant to ether. In a number of cases it had been administered for him, preceded by nitrous oxide gas, by Dr. H. W. Carter, with very satisfactory results, though at the same time he still noticed many disagreeable features attending its use. The proper administration of any anesthetic requires an expert; especially is this true of ether. Chloroform is the anesthetic to be used in operations about the head, face and neck. Here the cumbersome apparatus employed for ether will be in the operator's way and moreover the field of operation is liable to become infected. With a Junker's inhaler chloroform vapor can be administered through a nasal or tracheal tube, and the operator is not interfered with. In operations about the thorax and abdomen also he thought chloroform preferable, because the respiratory movements were not so much disturbed as when ether was used. He did not believe that death from chloroform was so sudden that there was no time to resort to restorative measures, as often stated. He had seen many cases, however, in which a fatal result was undoubtedly averted by the prompt recognition and treatment of unfavorable symptoms, such as extreme pallor, shallow respiration, cessation of capillary oozing, diminished force of the heart's action, and dilated and inactive pupils. He had never been careless with chloroform. He knew its dangers, and had taken every precaution to avoid them. In nervous, frightened and exhausted patients and in alcoholics he had frequently thought it advisable to give morphine and strychnine subcutaneously preceding the anesthetic.

**The Relation of the Anesthetist to the Patient and to the Surgeon.**—This was the title of a paper by Dr. S. Ormond Goldan. He was firmly convinced, he said, that not until the anesthetist is fully recognized by all concerned as entirely separate from the surgeon, would anesthesia ever advance. When we come to consider his relation to the patient, we are met by the superficial assertion that there is no relation whatever between the two, and that the anesthetist is simply the assistant of the surgeon. If the necessity for the operation did not exist, it is contended, there would be no need for the surgeon; but to this it may be replied that without the anesthesia many lives would be sacrificed and all major work rendered largely impossible. Furthermore, it is argued that the surgeon has always assumed the entire responsibility for the operation, and that usage makes this condition of affairs correct. It is, however, precisely this assumption of responsibility, to which the surgeon has no right and which should not be expected of him, that has delayed the recognition of this important branch of medicine. As to usage, this has constituted the only excuse for some of the most outrageous customs in existence. A division of the responsibility, Dr. Goldan believed, afforded added security to the patient, while it was also just to the surgeon, who thus had the assurance of a cooperator of greatest potentiality in the success of his operative work and the patient's return to health. This direct relation of the anesthetist to the patient entails a proper examination of the patient by himself, and by such examination valuable points in reference to the anesthesia are often discovered. The selection of the anesthetic and method of administration, which from the nature of the case must be varied, should be largely the anesthetist's province. His direct relationship to the patient naturally obliges him to take every precaution during the administration, and, in addition, to be ready with measures for the treatment of shock. It has always seemed to him that anesthetic and surgical shock are so closely related that it is the duty of the anesthetist to be prepared to combat shock, no matter in what form it is manifested. The safe completion of the anesthesia, the minimizing of its after-effects, and the subsequent good condition of the patient must be intensely satisfactory to the an-

esthetist, as it is to the surgeon. The relation of the anesthetist to the patient being direct, he receives what he is justly entitled to, and no more; the full credit for his own work and a fee in accordance. As to the relation of the anesthetist to the surgeon, Dr. Goldan said that he had early recognized why anesthesia occupied such an inferior position, this being simply a question of fee. Any measure having for its object the greater safety of the patient and the more successful outcome of the operation was heartily endorsed by the profession, but not so a corresponding increase in fee. The customary fees for years previous were all for the surgeon, practically nothing for the anesthetist. Who fixed the anesthetist's fees? Certainly not himself. The idea of fixed fees must have been on a par with the belief, so long prevalent, that any one could give an anesthetic. As surgeons' charges are not fixed, there was no moral or legal reason why those of the anesthetist should be. As for himself, when asked as to this point, his reply was that his fees are from no charge in appropriate cases to anything the circumstances of the patient could justly afford. To fix an invariable charge for the surgeon would be as unjust as it would be impossible—the same practice must obtain with the anesthetist. It is a fact that the surgeon's charges are based principally on the financial standing of the patient. Considering the amount of work done gratuitously by the great mass of practitioners, it was his belief that the medical man is entitled to a maximum fee in every case treated. As, however, this in many instances would be a burden to the patient, the practitioner follows the beneficent plan of making his charges in keeping with the latter's circumstances. He does not overcharge the rich, but undercharges the poor.

In all cases operated upon the ethical responsibility is the same for the anesthetist as for the surgeon. From every standpoint, indeed, the two are upon an exact equality. This must be recognized sooner or later, and the signs of the times indicate it now. He had also realized at an early day that to practice anesthetization to the exclusion of other work involved an incompatibility of practicing medicine generally. If not, there must be for the anesthetist a sacrifice of principles and self-respect for the so-called patronage of the surgeon. As long as the operator can use the anesthetist to magnify his own work and minimize the other's, just so long will he continue to give him work, as he calls it. While, however, "any one can give an anesthetic," so can any one operate; but results secured in anesthesia, as in operation, depend much upon the man. Frequently in his experience the physical condition of the patient had been so poor that only by the variation of the anesthetic and the most painstaking care could the operation have been successfully concluded, and he was quite sure that in a number of instances it was only by the extremest attention to details during the conduction of anesthesia that the patient's life had been saved. He preferred to confine himself to medical work in which his individualism was not sunk in that of another, and therefore when any agreement to conduct an anesthesia was entered into by him, it was only when the principles indicated in this paper were subscribed to.

Many surgeons lose sight of the fact that the anesthetist by education and training is his professional equal. The anesthetist exerts his energies to secure a featureless narcosis, the surgeon his for a successful operation; both of necessity working hand in hand, the patient's welfare being the chief object sought. Having gained this, their relation ceases, the anesthetist and the surgeon's relations being then directly with the patient. Dr. Goldan said he had been accused of endeavoring to make anesthesia of too much importance. To this accusation he pleaded guilty. He had always urged the importance of this subject, but consistently as regards every phase of it. Could too much importance, be asked, be given a subject so intimately associated with life itself, as anesthesia was? Many of his experiences as a specialist in anesthetics had been as instructive as they were entertaining, and what was most singular, they were often with those who prated much about ethics—ethics for others, but not for themselves. Similar experiences had been met with by others in all parts of the country from whom he had had communications. In conclusion he said he desired to express his appreciation to those practitioners who during their cooperation with him had shown that they had a proper conception of this subject.

**Cocaine Anesthesia.**—Dr. E. D. Fisher thought that spinal cocainization should be resorted to only in cases in which special circumstances contra-indicated other forms of anesthesia. In fractures of the spine, in which it would have been dangerous to practise subarachnoid injection, he had seen good results from the local injection of cocaine.

**Hypnotic Anesthesia.**—Personally Dr. Fisher's experience was against the use of hypnotism for anesthetic purposes. In one case in which it was employed for the reduction of severe contraction of the knee, just at the crucial moment of the operation the patient awoke to a realization of the most exquisite pain.

**The Surgeon and the Anesthetist.**—In his paper Dr. Goldan had placed the anesthetist on the same level with the surgeon, but he thought this was not altogether a correct position. The importance of having a specialist to administer the anesthetic, it seemed to him, depended on the character of the operation. The fee also, he believed, should be in accordance with the character of the operation, rather than with the length of the patient's purse. The anesthetist should, of course, be properly compensated for his services, but he would hardly place these on the same level as the surgeon's.

**Nitrous Oxide Gas.**—Dr. H. W. Carter said he had tried ethyl chloride as a general anesthetic, but found it less satisfactory than nitrous oxide gas. The use of the latter as a preliminary to etherization constituted an almost ideal method. No one anesthetic was to be preferred in all cases, but the nitrous oxide and ether sequence had many advantages. As a rule, it was the safest and best form of anesthesia, and when it was employed, very much less ether was required than when ether was given by itself.

**Morphine Objectionable.**—The preliminary administration of morphine had the effect of prolonging the narcosis. It was also apt to greatly increase the tendency to vomiting. If the patient was in good condition, it was not advisable to give any stimulant before anesthesia, and in general he thought it the best plan to wait until stimulation was actually needed before resorting to it.

**Good Results from Spinal Cocainization in Children.**—Dr. J. T. Gwathmey said that in Dr. Bainbridge's first thirty cases of spinal cocainization among children at the Randall's Island Hospital none of the unpleasant effects from this method noted by other operations was observed either during or after the operation. In one of the patients headache was caused, which lasted for two days, but that was all.

**Nitrous Oxide and Ether.**—As a rule, however, ether or chloroform was undoubtedly preferable. Now that the practice of using nitrous oxide gas as a preliminary to etherization had come into comparatively general use, he thought that the mortality statistics of ether would have to be revised. This method was so agreeable to the patient and was attended with so many

other advantages that it seemed almost criminal not to employ it wherever it was admissible. One of the principal objections to ether was its deleterious action on the kidneys, but, in consequence of the much smaller amount of the drug required when nitrous oxide was used first, he believed that this would in great measure be obviated. It was a fact that where we formerly had to give ounces of ether, we now gave only drams.

**Nausea and Vomiting.**—The nausea and vomiting so often seen after ether were apparently largely due to the impression on the olfactories. As the patient was coming out of the anesthesia, therefore, he thought it advisable that he should be allowed to inhale some substance, such as Cologne water, which had a pleasant odor, but which should not be too sweet. In this way we could do away with the saturation of the mucous membranes by ether.

**Local Anesthesia.**—Dr. A. E. Gallant said that in the local use of cocaine the trouble was that the injection was usually made under the skin or into the cellular tissue, instead of simply under the epidermis. If properly employed, about the same anesthetic effect could be obtained by the simple injection of sterile water, as it had been shown that this effectually obtunded the sensitive nerves.

**Small Doses of Morphine Advantageous.**—As to general anesthesia, much depended on the way in which we prepared our patients. It was his practice to give $^1/_{32}$ or $^1/_8$ grain of morphine (according to the size of the patient) one hour before operation. This small amount had the effect of quieting the respiration and the heart, and rendered the patient comfortable and cheerful.

**Nitrous Oxide Gas.**—As long ago as 1892 he began to use nitrous oxide as a preliminary to ether, and some of his experiences with it had been by no means pleasant. Under the excitement caused by it a vigorous patient could certainly occasion a great deal of trouble. It seemed to him that the day would come when this agent would be regarded as not altogether as harmless as was now generally supposed.

**The Administration of Ether.**—Personally he did not believe in cumbersome forms of apparatus. Without them he could maintain anesthesia for as long a time as was required for any operation, and yet with comparatively little risk. In giving ether he was accustomed to use the Allis inhaler, by means of which the ether is very thoroughly mixed with air, so that the patient does not suffer from the suffocation usually felt at first inhaling and does not have to breathe the same air over and over again. Being warm, the vapor does not irritate the lungs. The nausea from ether is largely due to the fact that after the ether has been carried through the circulation, more or less of it is excreted into the stomach. Hence the patient should be well washed out when the anesthesia is completed. He should drink plenty of hot water, and a saline injection should be made into the bowel. The stomach tube may be used for washing out the stomach, if desired.

**The Position of the Anesthetist.**—As to the fees received by the anesthetist, it had been his rule to allow him 10 per cent. of the amount charged for the operation, and this seemed to him an equitable arrangement. He did not think the anesthetist was in the same position as the surgeon, of whom more was required. The anesthesia specialists were undoubtedly deserving of great credit. They were doing good missionary work, but if they insisted on advancing unwarranted claims they would find their occupation gone. The result would be that this branch would be properly taught in all our medical schools and that their graduates would consequently be competent to administer anesthetics in a satisfactory manner.

## BOOK REVIEWS.

Diseases of the Liver, Pancreas and Suprarenal Capsules. By Leopold Oser, M.D. of the University of Vienna; Edmund Neusser, M.D., of the University of Vienna; Heinrich Quincke, M.D., University of Kiel; G. Hoppe-Seyler, M.D., University of Kiel. Edited with additions by Reginald H. Fitz, M.D., Harvard University and Frederick A. Packard, M.D., Philadelphia. W. B. Saunders & Co., Philadelphia, New York, London.

The present volume of the American edition of Nothnagel's encyclopedia of practical medicine reflects great credit on the American editors as well as on the publishers. Almost needless to say, Dr. Fitz has distinctly added to the value of the sections on diseases of the pancreas and of the suprarenal capsule. He modestly states that it has been his privilege to avail himself of the writings of Körte and of Mayo Robson, but his own additions are even more distinctly of value than any cited from others. Other American work of very high order has been incorporated in this present edition. Opie's observations on degeneration of the Islands of Langerhans in connection with diabetes is the most important of these additions, though it scarcely surpasses in interest Flexner's observations of fat necrosis. This volume contains also an account of the therapeutics of the suprarenal capsule and the active principles of these glands as studied in the last few years by Von Fürth and Takamine.

The section on diseases of the liver was edited by the late Frederick Packard, of Philadelphia, and as he was well known as a thoroughly competent and faithfully conscientious student of diseases of the liver these chapters have been brought well up to date. Dr. Packard's work in this volume represents almost the last medical writing that he did and some of his acute editorial observations and additions must stand as one of the worthy monuments of a brilliant young medical man cut off untimely.

This whole volume leaves nothing to be desired in the way of completeness of information, orderly arrangement of the text, thoroughgoing up-to-dateness, handiness for reference and exhaustive discussion of the subjects treated. The book is a noteworthy addition to American medical literature and well deserves a place in the library of every progressive physician.

American Edition of Nothnagel's Practice.—Diseases of the Stomach. By Dr. F. Riegel, of Giessen. Edited, with additions, by Charles G. Stockton, M.D., Professor of Medicine in the University of Buffalo. W. B. Saunders & Company, Philadelphia, New York and London.

The present volume of the Nothnagel series keeps up the good work previously noted in this edition and makes it clear that between the American editors and the publishers this greatest of modern text-books of the whole subject of medicine is to have a worthy presentation to the English-speaking medical public. As in previous volumes, the work of the American editor constitutes a distinct addition of noteworthy value to the work of the original European writers.

The book-making in this volume is well up to the highest standard. The illustrations are well reproduced and add not a little to the value of the text. The illustrations of the various malpositions of the stomach, as seen by shadows on the abdominal wall after dilatation of the stomach by gas inflation, are especially helpful in the understanding of the symptoms and course of the conditions and of the indications for treatment.

All the methods of gastric diagnoses are thoroughly

exploited and a number of the editorial notes in this part of the work serve to bring the book down to the very latest date in medicine. The American editor has also introduced valuable hints from recent advances in therapeutics. The employment of adrenalin chloride for instance, in hemorrhage from the stomach, which was unknown to the European writers at the time of the issue of the German edition, finds its due place here. In the discussion of other drugs, notably bismuth, morphine and atropine, the editorial notes are of special value and contain many excerpts from recent literature.

There is perhaps a suggestion that would make these books more handy. With the present rather thick paper the volumes are bulky and liable to deteriorate easily from use; yet it would seem that they should be available for frequent reference for many years.

The Buckeye Doctor. By William N. Pennell, M.D. The Grafton Press, New York.

The physician in fiction is growing very popular, especially the true and noble, unhonored man, who gives his life to the simple countryfolk, and wins a bare living and their gratitude in return. Since the days of Ian MacLaren's "Country Doctor," this type of old-fashioned physicians is being worked into every story.

It is, therefore, something of a relief, as well as something of literary value, to find a humorous series of pen-sketches describing the crude and ignorant physicians of our own country a few decades ago.

"The Buckeye Doctor" deals with a situation and an environment much like that made famous by Edward Eggleston in his "Hoosier Schoolmaster."

A young, ambitious man, fairly well educated, and decent in his behavior, tries, as did many such some thirty years ago, to let his light shine in the midst of medical darkness, and barely escapes having it extinguished altogether.

Dr. Pennell does not tell us that the pages are autobiographic, but as they originated in a series of letters to his daughter while at college, we may feel sure that the conditions he describes, and the local coloring, as well as the vernacular give us a faithful representation of scenes that were once familiar. Though happily they are now in the past, there is nevertheless a distinct literary reason for preserving them. The thread of the story becomes woven into a very good and exciting plot, and innocence triumphs and the villain gets his deserts. But the chief interest to the physician is in the details that must have been jotted down from an observant memory of conditions that will become rarer each year.

Ambulance Work and Nursing. A Handbook on First Aid to the Injured, with a Section on Nursing. Profusely Illustrated. W. T. Keener & Co., Chicago.

This work, which is anonymous, is evidently written by one of large practical experience. We are told in the Preface that it was written by a specialist whose connection with ambulance work in this country entitles him to speak with authority upon the subject and the views set forth are the result of personal experience in the rendering of First Aid, coupled with a long acquaintance with the system of teaching employed by the leading ambulance associations of the world.

The value of prompt and intelligent assistance in many cases of accident or injury cannot be overestimated, as the comfort or even the safety of the sufferer may thus often be assured, pending the arrival of the surgeon or the removal of the patient to the hospital.

The industrial conditions of modern life, the introduction of vast intricate and often dangerous machinery in almost every field of labor has served to materially magnify the risks to life and limb, which are inseparable from many occupations. The number of accidents constantly occurring from diverse and almost innumerable causes emphasizes the importance of prompt and immediate aid to the injured.

It is the object of this work to diffuse among the masses some knowledge of their own bodies and to teach them how to act in rendering effective aid in such emergencies until the arrival of skilled medical assistance.

As the work is designed chiefly to meet the wants of the laity, the terms employed are as simple and non-technical as possible, and the general directions as to the management of the case, what is necessary to be done, and how to do it, are plain, clear and readily comprehensible.

An outline of the anatomy and physiology of the human body is given, followed by directions as to the management of cases of hemorrhage, wounds, fractures, dislocations and other injuries, burns, scalds, poisonings, the removal of foreign bodies from the eyes, ears, and nose, etc., with a chapter on the carrying of the injured to the hospital and stretcher exercises.

The second part is devoted to nurses and nursing, massage and allied forms of treatment, concluding with a chapter on bone setting and bone setters.

The photographic illustrations are original, and for the most part, are of especial excellence. The proper methods of bandaging, the application of different forms of bandage, the use of splints, etc., are photographed from the living subject and convey more clearly what is sought to be conveyed than any amount of descriptive text. The general make-up of the book is handsome and attractive, the typography is excellent, the binding durable and the size convenient.

How to Keep Well. An Explanation of Modern Methods of Preventing Disease. By Floyd M. Crandall, M.D. Doubleday, Page & Company, New York.

There has been no class of literature so much abused by the quack and so little cultivated by the educated man as popular medical writing.

In it the charlatan has found a rich mine and the various popular health journals that are springing up over the entire country are evidence of a great need heretofore pandered to by truculent and money grubbing shysters. Even the popular works on medicine have for the most part been beneath contempt.

It is a healthy sign then of enlightened publishing spirit to find a readable and scientific work on popular medicine written by an author of acknowledged standing and of high literary and scientific attainments.

Dr. Crandall has written a very excellent popular work on medicine. One that can with profit and propriety be recommended by the profession to the laity. He discusses the general causes of disease, and then takes up some of the modern modes of treatment by vaccines, antitoxins, etc. Modern surroundings and their relationship to disease is well written and such miscellaneous topics as Rearing of Children, Diet for Children, Heredity, Regimen for Adult Life, Dangers Common to Middle Life, The Sedentary Life, Age and its Advancement, are all full of good counsel and interest.

We recommend this work unhesitatingly to our readers and wish for it a wide and hearty reception by the public, medical as well as lay.

# THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 83. NEW YORK, SATURDAY, AUGUST 15, 1903. No. 7.

## ORIGINAL ARTICLES.

### A REVIEW OF SOME OF THE RECENT LITERATURE OF THE ETIOLOGY, PATHOLOGY AND PROPHYLAXIS OF HYDROPHOBIA.*

BY FIELDING LEWIS TAYLOR, M.A., M.D.,

OF NEW YORK;

SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE HUDSON STREET HOSPITAL.

SOME years ago I heard a professor in one of our American medical schools say, in referring to Pasteur, that he was indeed a poor man who could not find a successful treatment for a disease which he had himself created. This skepticism in regard to the existence of hydrophobia in man, strange as it may seem, is still entertained by a few in high places. I cannot answer these men better than by saying that their contention shows complete ignorance of the literature of the subject.

The disease was first described by Aristotle, again by Celsus; in 1767 by Mead; in 1771 Van Swieten distinguished the violent and paralytic forms; Morgagni also describes it, also Gohier in 1811; Grüner in 1813 found the saliva to be the vehicle of infection; again Berndt described it in 1822; Galtier in 1871 produced the disease in rabbits; in 1880 Nocard and Paul Bert began to investigate it in the laboratory. They proved that the poisonous part of the virus would not pass through a filter of porcelain. This brings us to Pasteur and his pupils.[1]

Hydrophobia is an acute infectious disease due to the inoculation of a specific virus, usually by the bite of a rabid animal. "In nine-tenths of the cases the disease is contracted from a dog, in a few cases from cats, very seldom from a fox or wolf."[2] Dogs and cats have the disease more frequently than wolves. Horses seldom have it, cattle are affected rather frequently, while pigs rarely contract it. This is probably due to the large amount of subcutaneous fat in the latter.[4] Epidemics have several times been reported among deer, and skunks suffer from the disease. Rabies can be inoculated in pretty much all warm-blooded animals and in birds. In Great Britain and Ireland the disease is practically confined to carnivora. Hydrophobia is said to have been produced by the bite of an animal not suffering from rabies. This is opposed to all we know of the origin of other diseases.[2] The dog may have had the dumb form of the disease or else had it in a very mild form. The saliva may be inoculated in a wound or on a mucous surface. Senn[3] recounts a case of his in which the saliva of a rabid dog was inoculated in a pimple on the face of a lady of rank and fashion who succumbed to the disease.

It has been produced by wounds occurring during the dissection of rabid animals. It has also been caused by eating the flesh of animals that had died of the disease. The milk of suckling animals and suckling human beings contains the virus. Bradford tells of a child in the West Indies that contracted the disease from its mother who was suffering from rabies.

The virus is found in the central nervous system, the peripheral nerves, the salivary glands, the pancreas, the lacrymal gland, the suprarenal glands, the mammary gland and perhaps in the seminal fluid. It is not found in the blood, the liver, the spleen or the kidney or urine. In air the virus loses its virulence in fourteen hours, in water in twenty to forty days, in glycerin in one month. It has been found in a dog buried for forty-four days and in a rabbit buried for twenty-one days. Such cases are exceptional.[1]

1. *Age and Sex.*—More males than females are affected, the proportion being about four to one. This is due to the risk of exposure and difference in dress. Two-fifths of all cases are under fifteen years of age.[2]

2. *Location of Bite.*—Bites upon the face and hands are far more liable to produce the disease than others both on account of these parts being uncovered by clothing and on account of the greater likelihood of the involvement of nerves.

3. *Statistics of Frequency after Bites by Rabid Animals.*—G. S. Woodhead[4] states that 16 per cent. of those bitten by rabid animals contract the disease. Bradford[1] estimates that from 10 to 20 per cent. contract it. Many authorities estimate the percentage to be much greater.

4. *Prevalence.*—The disease is fairly prevalent among animals in certain localities while it is entirely absent from others. Among the former may be mentioned especially Lancashire in England, also Ireland and certain parts of France and Germany, while it is not found in Australia and Norway. It has been introduced by sporting dogs into countries where it was formerly unknown.[1]

5. *Period of Incubation.*—The period of incubation varies in man, according to Bradford, from a minimum of twenty days to sixty days, while it is probably unknown after six months.[1] Other authors have given twelve months, two and even five years as extreme limits. Gowers[2] considers it certain that the disease has developed after a year or eighteen months and will not deny the possibility of a longer interval. This period seems to vary according to the susceptibility of the patient, the virulence of the disease in the animal inflicting the bite, the amount of virus introduced and the position of the bite.[4]

6. That the disease is due to a living organism which affects the nervous system chiefly is almost beyond doubt. The long period of incubation

* Read before the West End Medical Society, April 4, 1903.

would tend to prove that the infective agent has to multiply in the tissues before it can produce its effects. Whether this agent be animal or vegetable has not been determined. It is scarcely necessary here to describe the many organisms that Gibier, Pasteur, Roux, Fol, Babés, A. Bruschettini and others have from time to time considered to be the cause of the disease. That it is not due to a previously formed poison we can be comparatively certain when we consider the difference in the action of the saliva of a rabid animal and the venom of a snake. Again the similarity of this disease to tetanus would suggest a similar causation.

*Pathological Anatomy.*—The blood is usually fluid, there is marked congestion of the fauces, pharynx, larynx and stomach. The stomach of the dog usually contains all kinds of substances, such as wool, hair, coal, wood, etc. Minute hemorrhages may occur beneath the pleura, probably being due to the asphyxia which usually precedes death. Some perivascular exudation of leucocytes may be found in the salivary glands and kidney. The brain, medulla and spinal cord often present marked congestion and very minute hemorrhages may be found. Microscopical examination of the cerebrospinal system will often reveal exudation of leucocytes into the perivascular spaces in different localities, minute thrombi, hyaline changes in and around the blood vessels, exudation of leucocytes around nerve cells, together with more or less marked changes in the latter, consisting in swelling of the cells, chromatolysis with the appearance of hyaline bodies and vacuoles.

These changes in the nervous system are most marked in the medulla, especially in the neighborhood of the pneumogastric and hypoglossal nuclei; they are next most marked in the cord, and least in the brain itself. Most authorities agree in considering these lesions as not characteristic. They are said to occur in other diseases and in certain cases of poisoning by phosphorus and arsenic. Babés[5] insists most strongly upon the importance of these perivascular and pericellular nodules and considers them of more importance than the gangliar lesions of Van Gehuchten which I shall presently describe. Subsequent investigations by several authorities do not seem to sustain him absolutely in the contention, and most investigators regard the following observations as having the most important practical relation to diagnosis.

In 1900 Nélis demonstrated before the Academy of Medicine of Paris certain changes in the peripheral ganglia of the cerebrospinal and sympathetic nervous systems that have the most direct bearing upon the nature of rabies.[6] If a spinal ganglion of a normal dog be examined it will be found to be composed of a peripheral zone made up for the most part of nerve cells and of a central part which is traversed by bundles of nerve fibers which join either the posterior root or a peripheral nerve. Between these central fibers there are some islands of nerve cells. Each one of these nerve cells is enclosed in a capsule. This capsule is composed of two layers, an external fibrous layer, and an internal layer consisting of a single row of endothelial cells. If a spinal ganglion of a dog that has died of rabies be examined, it will be found that a number of these nerve cells have more or less completely disappeared, while their place is taken by numerous small cells regularly arranged and having their origin in a proliferation of the endothelial cells lining the capsule.

By examining different sections, progressive degenerative changes in the nerve cells may be noted. These consist chiefly in chromatolysis, or solution of chromatophile substance, which is more or less complete. Nuclear changes vary likewise from cell to cell. The most frequent changes are hypertrophy of the nucleolus, hyperchromatosis and fragmentation of the nucleus. These changes in the nerve cells may be met with in different degrees in all the cells of the cerebrospinal axis and are not characteristic of rabies. The proliferation of the endothelial cells of the cell capsule, however, is regarded by Van Gehuchten and Nélis[7] as being pathognomonic of this affection. Besides the changes in the cell and its capsule there are present also dilatation of the blood vessels and perivascular exudations of leucocytes. These lesions are most marked in the plexiform ganglion of the pneumogastric. They are often absent when a dog is killed before the paralytic stage. They are often absent in experimental rabies when virus from the medulla of a mad dog is injected subdurally, and are usually absent when fixed virus is administered in the same manner. Nocard considers this method as most valuable on account of its simplicity and the rapidity of its application. These lesions have been fully verified by Cuillé and Vaillée, McCarthy and Ravenel and many others. The animal should be allowed to die or not be killed until the paralytic stage of the affection.

When a person has been bitten, it is the duty of the physician to look up the dog. If it happens to be a stray dog, of which all trace has been lost, Van Gehuchten[8] advises that the Pasteur treatment be at once resorted to. If the bite has been made by a known dog that does not as yet present symptoms of rabies, he should be confined for a few days. The saliva is virulent only twenty-four to forty-eight hours before the appearance of symptoms (Nocard, Roux). Generally these lesions will exist after the dog has become dangerous. The dog will usually live only two to five days, when a pathological examination will be most likely to give definite information. Of 44 cases examined by Degive, 37 had rabies and showed the changes, 7 did not have rabies and did not show them. J. Crocq and others have called attention to the similarity of the changes in the pneumogastric and other ganglia occurring in other diseases, especially diphtheritic croup. In diphtheria, however, the lesions are only capsular while in rabies they are both vascular and capsular. He calls attention to the similarity of

conditions in the pneumogastric in the asphyxia of the two diseases.[9] Nocard said, after verifying the work of Cuillé and Vaillée, that he knew of no disease up to that time in which precisely similar lesions had been found.

In a recent paper, D. J. McCarthy and M. P. Ravenel[10] of the Wm. Pepper Clinical Laboratory (Phœbe A. Hearst Foundation) report concerning 105 animals suspected to be rabid; of these 75 were dogs, 11 cows, 2 horses, 2 cats, 15 rabbits (experimental); one of the cows was also experimental. Forty of these cases were controlled by inoculation into rabbits, while many of the dogs were kept at the Veterinary College of the University of Pa. for many days. In 60 of these cases both the medulla and intervertebral ganglia were examined; in 36 only the ganglia, and in 7 only the medulla. In only 2 cases did they fail to find the lesion of Babés in the medulla when the changes in the ganglia were marked, but in several the bulbar lesion was slight. The vascular tubercle of Babés was much more frequently found than the one having the nerve cells as a starting point. Of 22 dogs *killed*, in 7 the authors would give no opinion. In 87 of 105 cases they were able to give a prompt diagnosis by examination of the ganglia alone, and in 94 by an examination of the ganglia and medulla.

The great advantage of this test is evident when it is considered that it may be done in tweny-four hours by hardening in alcohol, or in one hour if frozen sections be made, while experimental inoculation in rabbits takes from twelve to fourteen days usually, and may take forty days or more.[1] To neglect no precaution, the clinical history of the dog should be carefully considered, his spinal ganglia and medulla should be examined and inoculation into rabbits be made.

GENERAL PROPHYLAXIS.

1. Stray dogs should be destroyed as they generally cannot be located and watched after the bite has been inflicted.

2. Literature should be disseminated among the police and people concerning the necessity of trying to capture instead of killing dogs that have bitten any one, or that are supposed to be rabid.

3. *Muzzling of Dogs.*—On account of the muzzling of dogs hydrophobia has rarely occurred in Germany. The deaths for 1894-'98 were only 4 or 5 in animals.[12]

"In the metropolitan district of London, in which the muzzling order is now in force, there were in 1889, 176 cases; in 1890, the number had fallen to 44; in 1891 to 28, and in 1892 to 3. This fall corresponded to and was continuous with the enforcing of the muzzling order. As soon as the order was allowed to lapse, a rise in the number of cases began and continued until the order was re-enforced. During the five years mentioned no fewer than 25 persons died of hydrophobia, and 147 cases were sent for treatment to the Pasteur institute."[4]

4. *Treatment of the Wounds.*—As the poison is but slowly diffused there is a fair chance of getting rid of it entirely if proper measures be at once resorted to. A ligature should be placed about the limb and cupping or suction be resorted to and a physician be called. Some recommend immediate excision of the tissues in the neighborhood of the wound. Should this be inexpedient it should at once be cauterized. Dr. Cabot, of our Board of Health, has detailed a series of experiments in regard to the value of various cauterizing substances. He finds that 91 per cent. of guinea pigs inoculated with medulla of rabid guinea pigs do not develop the disease if their wounds be cauterized with fuming nitric acid at the end of 24 hours. Nitric acid is better than the actual cautery, and this in turn is better than nitrate of silver. In the case of small wounds he considers cauterization with nitric acid to be all that is necessary.

5. *Prophylactic Inoculations.*—About a score of years ago Pasteur discovered that the virus derived from the spinal cord of a rabid dog was attenuated by keeping. He also found that rabic virus could be attenuated by passing it through a series of monkeys until it became powerless to produce death. By passing this attenuated virus through a series of rabbits its virulence could be entirely restored. He also found that by passing the virus of a rabid dog through a series of rabbits (100) its virulence could be augmented, so that the ordinary incubation period of from fourteen to twenty days could be reduced to seven or even six days. This was the strongest virus obtainable which he termed *"virus fixe."* He first succeeded in a measure in producing immunity in dogs by the use of virus attenuated by passage through various animals. This system was difficult, uncertain and only partially successful. Later, assisted by Roux and Chamberland, he cut a series of cords of rabbits dead of injections of *"virus fixe"* into short sections, which he exposed to the action of dry filtered air at 72° F. for different lengths of time. He found that the cord removed after twenty-four hours was but slightly reduced in virulence, that removed after forty-eight hours was somewhat more reduced in virulence, and that the virulence gradually diminished until at the end of two weeks the virus was incapable of producing rabies. Now he injected an emulsion of the fourteen-day cord into a dog that had been bitten by a dog known to be suffering from rabies; this was followed by an injection of the thirteen-day cord and so on until the unattenuated cord was injected. By following up this system he proved that not only could a dog be protected against the bite of a rabid dog inflicted some days beforehand but that he could be protected against the fixed virus administered subdurally.

In 1885 this system was applied in the case of Joseph Meister who had been bitten by a mad dog. He was alive and well after five years. There are now used at the Pasteur Institute two methods known as the "simple" and the "intensive." In both methods cords are employed in increasing strengths until the three-day cord is finally

administered subcutaneously. In the simple method 19 injections are given in fourteen days. The intensive method is used for specially severe lacerated bites on the face and in the vicinity of large nerve trunks, and in the case of bites by wolves. This method consists in the administration of 28 injections in twenty-one days. Here the number of injections which, in the simple treatment, are spread over five days, are made in three days; then, on the fourteenth day, a fresh series of injections or rather repetitions, is begun which lasts until the twenty-first day.[4] The Board of Health of this city now makes prophylactic injections as well as pathological examinations, and inoculations for purposes of diagnosis.

Time prevents me from giving but a few statistics. I shall give only a summary of the cases treated at the Pasteur Institute, Paris, from 1886 to 1895 inclusive. If the cases be excluded in which the disease declared itself within a fortnight after completion of the treatment, there are 17,337 cases with 83 deaths, a mortality of 0.48 per cent. If all the cases be counted in which treatment was completed, we find 17,385 cases with 129 deaths or 0.74 per cent. Ten cases died during treatment, so that in all there are 17,395 cases with 139 deaths. Now Bradford's[1] conservative estimate gives the mortality of those bitten by dogs adjudged to be rabid at from 10 to 20 per cent. If we make even more than due allowance and place the mortality at 5 per cent., we find that among the above-mentioned cases we should have had 869 deaths, more than six times as many as we actually find after the Pasteur treatment.

Granted that a few have perished from the treatment, its inestimable value is beyond question. Many eminent authorities, however, agree that the treatment is absolutely harmless. It received the endorsement of a commission, of which Victor Horsley was chairman, appointed by the British House of Lords to inquire into Pasteur's methods.[14]

*Serum Therapy.*—We come now to an aspect of our subject which promises much. The difficulty of finding an antirabic serum can be appreciated when we consider that the germ of the disease has not been isolated, so that we do not know whether we have to find an antitoxin, a bacteriolysin, a precipitin or a combination of these substances. The first work along this line was done by Babés and Lepp in 1889, later by Tizzoni and Schwarz and then by Tizzoni and Centanni. In 1895, after six years of study and experiment, Tizzoni and Centanni published their work. In their experiments they used virus attenuated by digestion with gastric juice, which method being introduced by Eusebius Valli in 1886, is known as the Italian method. The latter found that digestion of virus by this method, while diminishing its virulence, in no way impairs its protective power. By making 17 injections in twenty days into a sheep (.25 gm. per kilo., of emulsion of nerve substance weakened by gastric juice) they found that after twenty-five days they had a protective serum of great potency. For revaccinations of the sheep they employed 10 injections in twelve days.

This serum cannot be increased in power beyond the point at which they arrived, but it can be maintained at a constant strength by repeating the inoculations from every two to five months. Moreover, it can be evaporated to dryness and will keep for months if protected from light.

Their typical serum (T. S.) is such that in proportion of 1-25,000 per kilogram weight of rabbit it will protect it against one infection unit of virus if administered subcutaneously twenty-four hours before the subdural injection of the virus is given.

An infection unit is the greatest dilution of any virus that will surely kill without any prolongation of the incubation period when .013 c.cm. per kilo. of animal is administered beneath the dura. The dose of virus actually used by them was .013 c.cm. per kilogram of canine virus diluted 1-50 which equaled .00026 c.cm. pure canine virus. They employed also two specimens of fixed virus, the first in a dilution of 1-5,000, and the second in a dilution of 1-10,000. Of the former the actual dose (.013 c.cm of dilution per kilo.) was 0.0000026 c.cm., and of the latter .0000013 c.cm. fixed virus.

One c.cm. of their serum (T. S.) neutralizes *in vitro* 1,200 infection units. On the eighth day 10 c.cm. of this serum protected rabbits weighing about 2 kilograms from a dose of canine virus twice as concentrated as was usually used for subdural injections, introduced into the sheath of the sciatic nerve.

On the first day after infection a dose of serum as much as five times greater than the protective dose is required, not to save the animal but only to postpone its death. On the eighth day the protective dose is to the curative as 1-10. The preventive against the virus of rabies is to the preventive against the fixed virus as 1-200. When the period of injection is postponed to the fifth to eighth day, Tizzoni and Centanni find that the curative dose has only to be multiplied some 8 or 10 times, whereas in diphtheria it must be increased at least 20 to 100 times, and in tetanus several thousand times. As in the case of tetanus, these authors found the subdural injection of the serum far more efficacious than the subcutaneous method. The subcutaneous dose of serum is 12,000 times as great as that by direct contact.

The great advantages of a serum become at once manifest, as one small dose is effective immediately, no special skill is required, and the dried serum can be transported to a distance. How long will the immunity last? The authors state that inasmuch as a sufficient dose always prevents the disease, it does not matter much how long immunity lasts. This method has not been applied to human beings so far as I have been able to ascertain, but it is certainly encouraging from a scientific aspect.

## HYDROPHOBIA: SYMPTOMS AND DIAGNOSIS.*

BY WM. BROADDUS PRITCHARD, M.D.,

OF NEW YORK;

ADJUNCT PROFESSOR MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, SMITH INFIRMARY, STATEN ISLAND.

The death within the past few months of the son of one of New York's most prominent physicians from what appears to have been unquestionably hydrophobia has attracted the attention of the profession and public with renewed interest to this most dreadful disease. Investigation resulting from this interest has developed the facts, according to official statements from the Board of Health, that the disease in both dogs and men, and also in horses, has shown a material increase during the past two years. It seems, therefore, appropriate as a subject for prompt and general discussion by the profession, and this Society is to be congratulated upon the alert wisdom of its President, Dr. Myers, who suggested it as the topic for this meeting.

My chief regret is that he was apparently unable to select any one better equipped in personal experience to present the subject to you. Such a dearth of personal experience and opportunity is both an advantage and a disadvantage. We are spared on the one hand the infinite distress attendant upon witnessing the agonized sufferings of such hopeless cases: on the other hand, we are robbed of the opportunities and inspirations which result from extended experiences and observations in the helpful study of disease. Possibly if hydrophobia were more frequent, it would be proportionately less terrible.

The disease is almost as old as medicine; it was certainly recognized and mentioned as occurring in dogs in the earliest records of medicine. Among the Greeks it was known as lyssa or lyssophobia. The worm (frenum) under the dog's tongue was supposed to be causatively related to the disease in some way. The term lyssophobia still occurs, especially among the Germans, its application to-day being largely restricted, however, to pseudo or false hydrophobia, the hysterical prototype or equivalent of the true disease. Is there a true disease? Are not all cases of so-called hydrophobia essentially hysterical? That people die with this symptom complex is not a final argument; that the influence of the mind upon the body is at times sufficient alone to arrest bodily function and cause death is abundantly proven by numerous experiments and facts observed in varied spheres of investigation. It is a curious fact in connection with the general subject that this has been a moot point, a vexed question since our very first knowledge of the disease. The pendulum swings from time to time from the extreme of unquestioning faith and acceptance to blind and extreme and dogmatic skepticism. In recent years the school of doubt has been most ably represented by no less a dean than Spitzka, whose experiments and observations seem to have convinced him at least that no such thing as hydrophobia exists, except as the product of a diseased and overwrought imagination. High in esteem as I hold any view or opinion entertained by so eminent an authority, I am compelled, in the light of what seems to me overwhelming and incontrovertible evidence, to accept hydrophobia as an actually existent medical entity and a frightful one at that. That the disease seems peculiarly and in extraordinary degree to be associated with an atmosphere of hysterical simulation and to inspire states of autosuggestion, must be admitted. One case of genuine hydrophobia in a community, especially if graphically described in the public press, will inspire fifty or a hundred examples of the pseudo type, and some of these latter may even prove fatal.

Infectiousness by example, so to speak, in nervous disease, is well known and admitted, as in chorea, hysteria, the various tics, etc. There seems to be a special and peculiar infection of morale in the atmosphere of this disease, possibly, and, indeed, probably explained by the horrible significance of symptomatic detail, and the utter hopelessness of the situation, both factors intensifying this mental impression.

Admitting the existence of hydrophobia as a disease entity, what are the symptoms by which it is to be recognized, and by what means are we to differentiate the true disease from the false and from other kindred affections? My confrère, Dr. Taylor, will pardon me if I necessarily encroach at this point somewhat upon his territory. I shall be as conservative as possible in my invasion. It is accepted as essential that the victim shall be infected extraneously—the dog, the cat, the wolf, skunk, and sometimes other animals, by biting introduce the virus of the disease. Within six weeks or six months, the wound having meantime healed apparently, in a normal way, the victim notices a lassitude, a malaise, and perhaps some slight feverishness with depression of spirits

* Read before the West End Medical Society, New York, May, 1903.

and nervous irritability, and simultaneously, as a rule, some recrudescence of irritation appears at the site of the original bite, slight redness with pain, and some stiffness or paresthesia is noted. This extends sometimes along the centripetal direction of nerve or blood vessel, or both, and at times the lymphatics are involved, and there is at this stage, termed the first great mental anxiety, a state of anxious apprehension and restless foreboding present, even in those who have forgotten a previous dog bite. Hydrophobia has been reported in idiots, and in the deaf and dumb. The temperature usually does not exceed 101 or 102° F., and may rarely be normal; the pulse is somewhat though not markedly accelerated, the face is alternately flushed and pallid, apparently as a reflex to the emotional equation. This, the stage of irritation, continues for two or three days, sometimes less, and ends abruptly in what is termed the convulsive stage. This second stage is introduced, as a rule, by symptoms indicating spasmodic difficulty in deglutition; stiffness of the neck muscles is complained of. On account of fever and hurried respiration, there is usually marked thirst and a consequent desire for water. Attempts to swallow the water are found to induce a spasm of the glottis and of the pharyngeal and neck muscles, the water being rejected by mouth or regurgitated through the nose. Repeated attempts produce the same result, so that finally the sight of water or the sound of running water will induce most distressing spasm of all the musculation of deglutition. Even the word "water" spoken in the hearing of such patients, or the washing of the face, may, by association provoke a spasm. The thirst increases, the patient tries again—again the result is the same. Can you imagine a more agonizing situation? Solids or semisolids can sometimes be swallowed, but by no means always. Sometimes the spasms become general—indeed, this is often the case—not only is the general spasm excited by efforts to swallow or by the sight or sound of water, but it may be excited by any source of reflex stimulation—a loud sound, a gust of wind, a touch upon the body anywhere may prove a sufficient exciting cause for generalized convulsions. Delirium may and often does ensue in the intervals. It is, however, sometimes absent throughout. Active hallucinations of any or all the senses, particularly of vision, may occur, and a state of exaggerated, almost frenzied terror may develop. The mental state is occasionally typical of acute delirium grave. After one, two or three days' duration this, the second or convulsive stage, gradually or abruptly passes into the third or paralytic stage. The pulse becomes weak, respiration hurried, general paralytic weakness supervenes and the patient quickly becomes stuporous and finally moribund, with evidences of pontine invasion and of pneumogastric failure. This stage rarely exceeds twenty-four hours in duration.

In many cases of rabies, as the disease is termed when it occurs in dogs, the first and second stages as described above do not occur, the dog passing at once into the paralytic stage. This variety is known as dumb rabies, and is said to occur occasionally, though rarely, in human subjects. Among symptoms specially noted by different observers, Watson particularly emphasizes a peculiar sobbing or shuddering respiration, such as is made by a person entering cold water. McCarthy and Ravenel call attention to an expression of terror not due to suggestion, as in both cases cited the patient was a young child.

The all-important problem in differential diagnosis is the distinction between true and false hydrophobia. It should never be forgotten that death has occurred from the false disease. In such cases the moral attitude of the attending physician, stimulated to firmness by conviction, may decide the issue as between life and death. The following points are more or less constant in the differential diagnosis. In pseudo or hysterical hydrophobia, the incubative period is either much shorter or much longer than in the true disease—symptoms developing earlier than a week or ten days, or even three or four weeks after a bite are suspicious, just as delay beyond five or six months is suspicious of the pseudo disease. It should not be forgotten however, that the true disease has developed within five days from the bite, and that it has been delayed for as much as twelve months. Symptoms developing within a day or two after a bite are almost certainly hysterical. The order of sequence in the hysterical disease is characteristic sometimes. There is no first and no second stage. The patient develops at once the second or convulsive stage. Hysterical hydrophobics nearly always show a disposition to bite those about them—very rare in the genuine disease; they also bark and growl and snap with much more imitative accuracy than in the genuine disease. To show them the dog that bit them, alive and well, is often a final test, the result being immediate recovery. Should the symptoms in any case last over seven days or ten days at most, this fact alone is almost conclusive as to the non-existence of the genuine disease. The crucial test, of course, is that of Pasteur inoculation.

From tetanus, often closely resembling hydrophobia, the latter disease is to be distinguished by the greater prominence of trismus; by the fact that the cause is a wound and not a bite; by the absence of mental symptoms; by the absence of remissions in the convulsions; by the absence of thirst, expression of terror, dribbling of saliva, and by the shorter period of incubation. In certain cases of acute mania, there may be gustatory hallucinations and fear of water. In such cases there are, however, no tonic or clonic convulsions, the patient may be induced diplomatically to drink, there is no history of the bite of a warm-blooded animal, and there are the other symptoms of mania.

---

**Female Physicians in England.**—There are about 90 female physicians in London and its suburbs. The Royal Free Hospital employs 16, and there are 70 women students in it. In all England there are about 600 women physicians.

## RABIES.*

BY H. D. GILL, V.S.,
OF NEW YORK.

From the time of Aristotle (322 B.C.) to the present day we have clear accounts of this disease existing through every age, and provoking fear and horror in many countries. It was caused by the bite of an animal and such animal was generally believed to be mad.

The medical and veterinary profession have always recognized the existence of such a disease as rabies in man and animals and also believed in its existence and contagiousness. It was not until the nineteenth century that by experimental inoculation it was shown that the dog which did the biting was actually rabid, and that the disease certainly resulted from the bite, and that the disease in the dog and man were identical. Notwithstanding the fact that it had been very clearly demonstrated by competent investigators that rabies may be easily communicated by inoculation from animal to animal and man to animal, there are many who still believe that hydrophobia is not a specific disease and is about as likely to follow the bite of a healthy dog as of a diseased one.

If the skeptics would only stop to consider that an animal cannot communicate a contagion it does not possess, the absurdity of spontaneous origin would be apparent. One might as well say that smallpox arises spontaneously and that the disease can be contracted from healthy persons.

Hydrophobia has been observed in the following species: dog, cat, horse, ox, donkey, mule, sheep, goat, hen, pigeon, wolf, fox, prairie dog, hyena, monkey, deer, skunk, rabbit, guinea pig, rat and mouse.

*Prevalence of Rabies.*—For years we have been led to believe that this disease was extremely rare. In 1900 Dr. D. E. Salmon, chief of the U. S. Bureau of Animal Industry, to determine the occurrence of rabies in the United States, wrote to a number of veterinarians and was surprised to learn that the disease existed in nearly every State and was evidently on the increase. City veterinarians who doctor dogs see many cases of rabies. During the year of 1902, 20 cases came under my observation, and four since last December. On two occasions I noticed small boys leading rabid dogs through the street. I believe if an accurate record of rabid dogs in the Borough of Manhattan could be had, the result would be startling.

In dogs hydrophobia appears in two forms, furious rabies and dumb or mute rabies. According to Pasteur, furious rabies occur when the brain is invaded by the rabid virus and dumb rabies when this reaches the spinal cord first. I have noticed that in many cases when an animal was bitten by a rabid dog on the head or face it produced the furious, and if bitten on the body or legs the dumb form developed. Three cases came under my observation during the month of January; two dogs and a horse all were bitten on the nose by the same dog and were subsequently affected with the furious form of rabies.

The furious form of rabies presents three periods: (1) melancholic period; (2) irritated period; (3) paralytic or terminal period. The duration of the first period varies from twelve hours to two days. During this time we notice a change in the patient's habits; he is depressed, gloomy, or anxious, defiant, restless, cross, and very irritable. He no longer obeys his master. He hides away, changes position suddenly. Some animals are exceedingly gentle and affectionate. In the beginning appetite is good but they soon refuse to eat. They lick cold objects or bite everything within reach and swallow foreign bodies, such as straw, coal, wood, feathers, pebbles, rugs, etc. We sometimes notice nausea and vomiting.

The second period, that of irritation, lasts three or four days and is characterized by spasmodic mad attacks, the restlessness increases and an irresistible force induces the patients to run away, covering great distances in a short time. They have a great inclination to bite and show no sign of fear; and rarely avoid people or animals, and when caged chew continuously on the bars, breaking their teeth or fracturing their jaws. At this change the bark is changed to a peculiar howl.

The third, or paralytic period, the animal presents a sullen and scowling expression, the lower jaw is paralyzed and hangs pendulous. The gait is staggering and he dies from cerebral paralysis or exhaustion from the fifth to the eighth day.

Dumb rabies is distinguished from furious rabies by the absence of the second period of irritation. The most characteristic symptom of dumb rabies is the dropped lower jaw, animal being unable to close the mouth, the tongue is hanging out, and there is dribbling of saliva. The membrane of the mouth is dry, discolored, and covered with dirt or dust. The lower jaw being paralyzed, the dog cannot bite, nor does it desire to; while in the third stage of the furious form when the jaw is also paralyzed, the desire and tendency to bite may be retained. The course of this form of rabies is short: death usually occurring in from two to four days.

The dumb form of rabies is very common and many cases are brought to the veterinary hospitals with the owners' suggestion that the dog has a bone in his throat, and in many instances we are unable to convince the owner of our diagnosis, who generally understands that a mad dog must froth from the mouth, be afraid of water, and raging mad. It is a dangerous error to suppose that the disease commences with such signs. Rabid dogs are not afraid of water, to the contrary, they lap and plunge their heads into it, some will even swim rivers. The symptoms appear very gradually and the only change noticeable is in the animal's habits and behavior.

Beware of a dog when it becomes dull and hides away, appears restless, always on the move and prowling. Whose countenance is somber and sul-

* Paper read before the Alumni Association of the Bellevue Medical College.

len, walks with head down like a bear. Beware of one who barks at nothing when all around is still. Beware of a dog that scrapes incessantly and tears up things. Look out for the dog which has become too fond of you, and is continually trying to lick your hand and face. Beware, above all, of the dog who has difficulty in swallowing, which appears to have a bone in his throat, and one that has wandered from home and returns covered with dirt, exhausted and miserable.

How inconsistent with modern preventive medicine has been the handling of this terrible malady, the most feared and dreaded disease of mankind. Knowing as we do the reality of rabies in dogs and that hydrophobia in man is caused by bites, the first thing that ought to appeal to the medical mind is to get rid of the dangerous dog, and prevent the transmission of this terrible disease. It does not appear that any effort was ever made in this city in that direction. The whole aim seems to be to apply the Pasteur treatment. Numerous so-called "Pasteur Institutes" have sprung up and from their prosperous condition I should judge that a great many more persons are bitten by dogs than we are aware of.

Rabies is relatively more common in New York because dogs are very numerous, and if suitable regulations are not adopted and enforced the disease will surely increase, and the health of the people be unnecessarily jeopardized.

By a law enacted some years ago, the American Society for the Prevention of Cruelty to Animals was given power to license and gather in and destroy all homeless and ownerless dogs. This private corporation enjoys a yearly revenue of many thousands of dollars from such unconstitutional tax, and the only service it has rendered the people is to catch all unlicensed dogs that their men may happen to run across; throw them all together into a wagon or automobile where they fight and bite until the wagon reaches the pound, where I am told the same thing is practised.

By their methods this Society may be accessory to the spread of rabies, for example: One of these dogs may be rabid and bite one or more of the others that may be later on reclaimed and taken home. Suppose in a few weeks he develops rabies and goes on biting other dogs or perhaps some person. This has happened. This method also exposes reclaimed dogs to other contagious, infectious, and parasitic diseases.

This same society refused a certain bacteriologist the opportunity of making a diagnosis of a supposed case of rabies in a dog that had bitten one or more persons. I was not at all surprised at this, knowing that the president of this society believes that there is no such thing as rabies, except in the imagination and he some years ago issued an article on rabies and hydrophobia, which was scattered broadcast over the country, stating that it was unnecessary to enforce regulations against rabies in animals. I noticed only the other day, in a newspaper interview, that he still holds the same belief.

It is high time that this very serious dog question should be taken out of the hands of a private corporation, whose only care seems to be to collect license fees, and place it where it properly belongs, under the municipal control of the Health Department.

Dr. Salmon states that there is no contagious disease more easily eradicated than rabies. As the disease can only arise from contagion, and the contagion is practically always transferred by a dog's bite, it suffices to stop the dogs from biting for a period sufficient to cover the incubatory stage of the disease, that is, for about a year, in order to stamp out the malady. As a scientific problem, therefore, the eradication of rabies is a very simple matter, but as a practical question it is one of the most difficult which confronts the sanitarian.

And this difficulty arises not from anything inherent in the work to be accomplished but in the opposition of those who own and keep dogs. The measures necessary for the eradication of rabies are two in number: (1) Destruction of worthless, ownerless, and vagrant dogs: (2) efficient muzzling of all dogs which appear upon the streets or in public places. The results which have been obtained by muzzling justify its enforcement wherever there is an outbreak of rabies.

In Berlin from 1845 to 1853 there came to the Veterinary School a yearly average of 35 cases, from March, 1852 to 1853 there were 82 cases, and from March, 1853, to the end of July there were 37 more.

On July 20, muzzling was generally enforced with the result that but 6 cases were reported during the remainder of the year. Only 4 cases were observed in the whole city during 1854, and but a single case in 1855. For the seven years following there was not a single case recorded.

In 1863 muzzling was relaxed and rabies gradually increased until 1875 a law was passed extending to the whole of Prussia, which provides that all dogs suspected of rabies shall be immediately killed, as also all animals which it is evident have been bitten by rabid animals, and that all dogs in a district which has been infected by an outbreak of rabies shall be confined, or, when abroad, both muzzled and led. After the enforcement of the above law no case occurred for about ten years. Fleming states that in Vienna rabies was entirely suppressed by eighteen months of stringent muzzling, but in 1886 the muzzling order was rescinded and badges had to be worn on dog collars instead; in the following half year there was only one case of the disease, but in the next half year rabies became epidemic, and the muzzle had again to be worn, with the result that the malady soon subsided and disappeared. The value of the muzzle in suppressing rabies has been perhaps best demonstrated in London on several occasions, especially in 1885. In the previous years hydrophobia had increased to a very alarming extent in England, and no steps worthy of note had been taken to check the mortality. For London alone in that year no

fewer than 27 deaths were reported as due to the bites of rabid dogs. A muzzling order was then enforced, and at the end of 1886 not a death was recorded. Unfortunately, the order prescribing the use of the muzzle was then rescinded, and in a few months a case of hydrophobia occurred in the south of London, soon to be followed by others, and in 1889, 10 deaths were registered. In July of that year the muzzling order was again issued and stringently carried out, and rabies and hydrophobia once more disappeared.

For absolute public safety the following measures are suggested: (1) To place the city dog handling under proper medical or veterinary jurisdiction; (2) to prohibit all dogs from running at large unless muzzled or, at least, muzzle all dogs in infected areas; (3) to provide separate compartments in the wagon and at the pound for each dog; (4) to provide safe and proper places for the keeping of dogs suspected of having rabies, especially if they have bitten other dogs or a person; (5) every dog bitten by a rabid animal should be destroyed or quarantined for at least one year.

## BEST METHODS TO PREVENT HYDROPHOBIA.*

BY FOLLEN CABOT, M.D.,
OF NEW YORK.

Hydrophobia is rarely seen in man, but commonly seen in animals, more particularly in the dog.

The disease is one about which much ignorance exists in both the mind of the physician and the layman. On this account, we are greatly handicapped in our efforts to stamp out the disease. Few physicians ever see a case of hydrophobia, and as a consequence, many medical men even doubt its existence. Such a belief adds to the confusion and ocasionally does irreparable harm.

We have in hydrophobia a disease as well established in its etiology and symptomatology as is typhoid fever. Until we gain an intelligent understanding of the disease, particularly its prophylaxis, we can accomplish little.

In the prevention of hydrophobia we have three distinct lines to work in: *First*, intelligent laws in regard to animals, particularly dogs; *second*, treatment of the injury by antiseptics and cauterization; *third*, Pasteur method of producing immunity.

We must bear in mind the fact that an animal develops rabies only after a bite by a mad animal. The disease never develops spontaneously in either man or animal. The season of the year bears no relation to the prevalence of rabies. In some statistics, recently gathered, the winter months showed the largest number of cases of rabies. This fact is quite contrary to the popular belief that summer is the season of the year to look out for mad dogs. Upon this erroneous theory many of our dog laws are based. For instance, in New York, dog catchers go out with great enthusiasm and capture stray dogs, beginning May 1 and continue to do so during the hot months. If we make laws which can be carried out all the year round, much good will follow. No dog without an owner should be allowed for a day in New York City. This matter of catching and mercifully disposing of dogs should be put in the hands of the city and vigorously and intelligently enforced every day in the year. We would soon reduce the enormous number of homeless and half-starved dogs seen in the city streets to-day. Every owner of a dog should be compelled to register his dog with a bureau for the purpose, and each dog should be quarantined for at least six weeks after being brought into the city. I believe that muzzling all dogs for six months would at present be desirable; but I do not believe it would be necessary to have such a law continued beyond the six months. In England, by a strict quarantine law against rabies, in one year the disease was reduced in dogs from several thousand cases to nine. There, dogs are absolutely quarantined by government officials for six weeks, and partially so for six months. This record shows what a strict law will do. It is erroneous to suppose that furious rabies is the usual form in dogs. Dumb, or paralytic rabies, is the usual type seen in New York to-day.

The treatment of a bite of a suspected animal is of much importance. If the bite is on the face, it is most serious; other exposed parts of the body, as the hands and arms, are next in importance. The microorganism of rabies, I believe to be fermentive in character, lying localized for at least twenty-four hours, and then infecting the system by way of the nerves and not directly by the blood. The extent of the wound has much less significance than its position and after-treatment. A wound no deeper than a pin scratch may be the cause of an infection. In 3 cases of hydrophobia out of 6 I have had under observation, the wounds were the merest scratches.

In cases of wounds about the face and exposed parts, the patient should be put under a general anesthetic, if necessary, and the wound scrubbed out with a brush, first with green soap, then with bichloride of mercury 1 to 1,000. This should be done as if for an operation. After this, fuming nitric acid should be carefully applied by means of a pointed glass rod. The wound should then be dressed surgically. If no anesthetic has been given, I usually use first cocaine after the scrubbing, then pure carbolic acid followed by fuming nitric acid. This must be done as early as possible; but I have demonstrated by careful experiments with guinea pigs that it is of value even as late as two days. At the end of twenty-four hours I have shown in a large number of guinea pigs that this method will save 91 per cent. of infected cases. If we cannot obtain nitric acid, the actual cautery is next best. It is, however, difficult to see each small point while using

* Read before Bellevue Alumni Society.

this agent. Nitrate of silver, which is so popular, saved only 55 per cent., and therefore should not be used. However, simply cleansing and scrubbing out the wound with soap and water had some effect, saving 31 per cent. of guinea pigs infected with rabic virus. In my series of experiments I found that about 13 per cent. of control animals infected with the virus did not develop the disease. This fact must be remembered, but it does not affect the general result of the experiments.

Treatment, therefore, of the wound, even at the end of forty-eight hours, is of distinct value, and when done within twenty-four hours, and properly done, I believe it to be of more value than the Pasteur method of protecting the system against possible infection. Both methods, however, should be used.

The dog in every instance should be preserved alive, if possible, and kept under observation for a week. Then, if it remains well, there is no danger. If the dog dies, the brain should be preserved for examination and inoculation tests with guinea pigs.

The Pasteur method of protecting the individual against hydrophobia was at first much opposed by the medical profession, but is now generally accepted and is no doubt of much value if begun early.

I shall not describe the Pasteur treatment here beyond saying that it usually lasts from fifteen to twenty-one days, according to the position of the wound and the interval elapsing between the time of the injury and beginning of treatment.

The preliminary treatment of the wound also is taken into consideration when deciding upon the number of Pasteur injections. Children seem more susceptible to the disease, perhaps because they are more commonly bitten in the face.

In closing, I make a strong appeal to the medical profession to study the subject more thoroughly and to act promptly in the preliminary treatment of injuries. But in case the disease develops, never give up hope, as a case has been known to recover. Gowers has reported one and I believe it to be a possibility.

In instances where the disease develops we must prevent the patient from suffering. This can be done by general anesthetics, chloral and morphine. The patient should not be allowed to suffer.

---

**Brucine in Chronic Morphinism.**—After having had unsatisfactory results with strychnine in morphine-habit, A. Fromme (Münch. med. Woch., July 7, 1903) resorted to brucine with much better success. One of two ways may be employed: either brucine is given internally in gradually increasing doses while the hypodermic dose of morphine is slowly diminished, or else both drugs are given internally. Not only does the brucine increase the solubility of morphine in the system and thus ensure absorption of the hard infiltrations at the site of injection and more rapid excretion, but it also stimulates circulation and digestion, prevents destruction of the red corpuscles and promotes sleep. The second method is generally to be preferred, since the use of the syringe, in itself an attraction, is at once done away with.

## ADENOIDS, IN RELATION TO AUDITION AND CEREBRATION.*

BY JAMES FRANCIS McCAW, M.D.,

OF WATERTOWN, N. Y.;

OCULIST, AURIST AND LARYNGOLOGIST TO THE CITY HOSPITAL AND JEFFERSON COUNTY ORPHAN ASYLUM; MEMBER OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY; JEFFERSON COUNTY MEDICAL SOCIETY; ETC.

Since the attention of the profession was called to hypertrophy of the pharyngeal tonsil, the subject has received much consideration and the literature is now voluminous.

In spite of all that has been said and written, there are still many physicians who are not informed as to the remote results of neglected adenoids, and permit children entrusted to their care to mature with incurable defects, which could easily have been prevented with the proper care in childhood.

To one of these—Disease of the Middle Ear—I wish specially to call your attention, and if in what follows I succeed in impressing upon you the importance of these growths as a causal factor in tubal and tympanic diseases, my time will have been well spent. That inflammatory or other obstructive conditions in the nasopharynx have an injurious effect upon the middle ear, is now universally acknowledged by all who are best qualified to judge. If we consider the anatomical relation of these growths, located as they are in the vault and along the posterior wall of the pharynx, filling the space between the Eustachian cushions, blocking the posterior nares and mechanically obstructing free nasal respiration, it should be an easy matter to understand the pathological relation between these and conditions affecting the auditory apparatus. Lymphadenoid disease is usually found in its highest stage of development during childhood, and in some cases is said to be congenital. This is accounted for by the fact that in children all gland structures are more prone to take on pathological changes, and in this particular region are stimulated to greater activity by the local inflammatory process accompanying the acute exanthemata in children. Now add to this the relatively small space in the pharyngeal vault of a child, and we have a picture which cannot fail to impress upon the minds of careful observers the importance of this condition as an etiological factor in diseases of the middle ear and also its influence in aggravating a diseased process already begun.

All investigators and writers on the subject give prominence to the occurrence of ear complications in adenoid disease. It is my opinion, based on observation and clinical experience, *that lymphoid tissue in the pharynx is the most important predisposing factor in acute and chronic suppurative and non-suppurative otitis media and recurring earache in children.* Indeed, the effect of lymphadenoid disease upon the function of hearing begins in childhood, increasing to ado-

* Read at the Annual Meeting of the Jefferson County Medical Society.

lescence and old age, until in many cases audition is almost destroyed.

How are these effects produced and what is the result on the growing child?

It is now quite generally conceded that any cause which interferes with free nasal respiration will in time produce impaired hearing. As a result of obstruction to the passage of air through the nasal chambers, free ventilation of the pharyngeal vault is interfered with, which necessarily produces a rarified condition of the air in this region. Reduction of air pressure is followed by a passive congestion and hyperemia of the mucous membrane, extending through the Eustachian tube to the middle ear. Following this there is swelling of the mucous membrane encroaching upon the caliber of the Eustachian tube, and interfering with ventilation of the middle ear, resulting in depression of the tympanic membrane. This limits the excursion of its vibrations and impairs the function. It is very easy to understand that an inflammatory process can readily be engrafted on a mucous membrane in such condition, and it is a fact of common observation that it does occur in a large number of these cases. Now, as an almost invariable law, where we have a catarrhal inflammation of the middle ear with hypersecretion, it sooner or later becomes infected and we have a suppurative process set up, which in consequence of the closure of the Eustachian tube due to the obstruction in the pharyngeal vault, is very apt to become chronic, carrying with it the possibility of a number of serious and often fatal complications. The location of the growth is important as a determining factor in ear complications. Adenoid tissue situated between the Eustachian tubes, although small in amount, is of far greater danger to the ears than a very much larger amount limited to the upper and posterior portion of the vault. A large percentage of children with adenoids become deaf, in fact, it is one of the most frequent causes of chronic "running" ears in young children. The result of these influences upon the development of the child is unfortunate in the extreme. These children are mentally deficient. A plausible explanation of which is found in the close anatomical connection between the veins of the nose and anterior lobes of the cerebrum. The venous congestion of the nasal chambers, always present from obstruction to nasal respiration, may induce a corresponding congestion in the anterior portion of the brain. The obstruction which these growths offer to the return of lymph from the brain may also act as a contributing factor. The great increase in the mental ability of some children immediately following a thorough removal of the growth goes a great way in substantiating the truth of the obstructive theory. There can be little doubt, however, that the stupidity is made more manifest from lack of attention than from deafness. It seems unnecessary for me to add that the restless and unrefreshing sleep, imperfect blood oxidation and impaired general nutrition, from which these cases usually suffer, are of more than ordinary importance in the physical and mental development of the individual. Children with adenoids are soon fatigued by mental work. The reproof and punishment, ridicule and censure to which the child is subjected in consequence of its deafness are very important factors in determining character.

The writer has tried to indicate in as brief manner as possible some of the conditions dependent upon lymphadenoid disease of the pharynx and call attention specially to its influence upon audition and cerebration, and to show that the mental growth of a child is commensurate with the state of healthful nutrition and physical vigor and point out why the disease under discussion lessens the vital powers and weakens the whole organism. The almost invariably rapid recovery and favorable effect upon the hearing and intellectual field from thorough surgical removal should impress upon us the importance of early operative interference.

## CHRONIC LEG ULCERS.

BY F. WARD LANGSTROTH, JR., M.D.,
OF NEW YORK.

This article is intended to outline a few methods of treatment that have been found effective, and to point out some mistakes to be avoided.

It is first necessary to consider some of the etiological factors concerned in the production of chronic leg ulcers, because the treatment will be found to depend very intimately on the factors active in producing the condition. The causes are given in the order of their frequency, based upon the records of almost two hundred cases, personally observed:

1. Varicose veins are by far the most frequent cause of this condition, and these may be divided into three classes:

(*a*) After varicose veins have existed for some time, and especially as the subject nears the later years of life, there appears a certain local dyscrasia in the affected leg. This dyscrasia is due, not only to the defective nutrition, resulting from the lack of pure blood and the removal of waste products, but also because the edema, usually accompanying large veins, tends to the production of an excess of fibrous tissue in the parts. A further loss of normal cell vitality is thus caused, due to a consequent pressure atrophy induced by the combined action of the pressure exerted by the edema and by the contracting fibrous tissue. Now, when an infection takes place in this particular devitalized tissue, either from excoriations produced by scratching eczematous areas, which so frequently accompany this condition; or from slight traumatism, it does not spread rapidly, but finds its field of action prohibited by this excess of fibrous tissue and defective cellular action. The process spreads slowly, and the same causes which prohibited its rapid extension also interfere with its ability to heal rapidly. And the chronic, slug-

gish leg ulcer results. (*b*) In younger subjects, where the varicose lesions have not existed so long, the chronic condition results from a primary acute ulcer. Infection takes place, and finding the tissues and circulation in a more nearly normal condition, spreads rapidly. A tissue reaction starts at once to overcome the invasion. A small round cell infiltration actively walls off the infected area and there results, by a process of proliferating embryonic tissue, a resultant fibrous tissue, which is produced by the struggle of the cells against the active spread of the infection; thus becoming the ultimate factor in producing the change from an acute to a chronic ulcer, in this second class of cases, because as the fibrous tissue contracts it shuts off, to that extent, the blood supply of the parts it surrounds. And so the formation of new tissue to take the place of that lost during the active process is prevented and thus a chronic ulcer is established. We do not consider that in this class of cases the veins take a very active part, except in the later stages, as the above condition may be aided because of the sluggish state of the superficial circulation. (*c*) In phlebitis and periphlebitis, which two conditions usually exist together, either one may occur as the primary state, the other following by reason of the diffusion of the inflammatory condition through continuity of tissue. An ulcer results when suppuration involves the cutaneous surfaces, and may resemble either one or the other of the above-mentioned forms.

2. In syphilis, we must confine ourselves to late ulcerative skin lesions of the lower extremity and gummata of the same, which result in suppuration and accordingly form ulcers. The latter are the most frequent and, of course, both are chronic.

3. Trauma when engrafted upon varicose veins very frequently results in the formation of chronic ulcers. That an ulcer resulting from traumatism in the absence of varicose veins is usually of an acute nature seems capable of ready explanation if the ideas expressed in the above paragraphs are acceptable.

4. Tuberculosis and leprosy, in this country at least, are comparatively rare, and could be more readily considered under chronic inflammations of the skin.

Let us now consider a few simple rules to be observed in the treatment of chronic leg ulcers: (1) Insist on the importance of a proper differential diagnosis, in which practitioners would seem to fail or at least to consider it of no value; (2) avoid all ointments and pastes, relying on aseptic or oftentimes in this condition antiseptic forms of treatment; (3) consider always local and general constitutional treatment; (4) do not despair. The ulcer that absolutely refuses to heal is exceedingly rare.

To continue this for the special treatment: In varicose ulcers we should remove as far as possible the cause. The radical and palliative treatment of varicose veins can be found described in all text-books of surgery. We, therefore, mention here only two measures that can be adapted, and thus indicate their usefulness. (*a*) Radical operative procedures, as just stated, are to be found described in text-books of surgery, but in no case do we think operation should be considered until the ulcer is entirely healed. (*b*) Bandaging, then, is the only means left by which we can control the causative factors in this class of cases. This is one of the most useful and in fact all important means of treatment. In no case use any form of elastic bandage or stocking while ulcers exist; because all such means of support cause to some extent an excess of heat and irritation of the parts. Unbleached muslin bandages 2½ to 3 inches in width and 7 to 8 yards in length are the best. In their application do not resort to a spiral reverse on the leg, for while it gives the most equal pressure, it invariably refuses to remain long in place. A properly applied figure 8 of the foot and leg, making all pressure on the up-turns, gives the best results.

In very sluggish ulcers, curette the surface and incise the edges. In the first class of varicose ulcers, the incision going well through the fibrous edge is amply sufficient for its mobilization. In the second class, where the ulcer is bound down and almost immovable, deep elliptical incisions must be made around the parts in order that they may become movable. These procedures must be accomplished under aseptic or antiseptic precautions, and the parts subsequently dressed for twenty-four hours with a saturated solution of boric acid in water, or hydrargyri chloridum corrosivum, 1 part to 10,000 of water. The purpose of these incisions is twofold (1) by cutting the fibrous tissue to allow the formation of new capillaries, which may supply the parts with blood; (2) by cutting the fibrous adhesions to allow the ulcer to contract toward its center.

Considering this to have been done, or, in the absence of its necessity, let us now resort to stimulating treatment. There are several solutions which lend themselves especially to this purpose. Ointments, except for rare cases, are to be avoided. Many of them are not aseptic. They prevent free drainage, which is bad, as ulcers are only indolent wounds. The bases of ointments, in fact any grease, are not conducive to the formation of granulation tissue, and their removal is likely to destroy as much of the new growth as could have formed since their previous application.

Solutions applied to the ulcers, on sterile gauze, will be found, in almost all cases, to be the better form of treatment. Let us then consider some of these solutions, each one to be mentioned in its order, being a little more stimulating than its precendent. Their formulæ will be given at the close of the paper.

A saturated boric acid solution is useful in those cases which readily become inflamed, but it is rather too mild for use in the majority of cases. (It must be remembered here as elsewhere that we are considering only chronic ulcers. Acute ulcers of course deserve very different treatment.)

Alum acetate in saturated solution is useful in

chronic cases that have become suddenly inflamed.

A 5-per-cent. to 10-per-cent. solution of ichthyol in water lends itself to the same uses.

Chronic ulcers must be stimulated in order that they may heal. In other words, more blood must be brought to them and all necrosed tissues and infective agents removed.

Red wash seems of especial value to bring about these results, and, applied every day, usually produces most marked changes in the character of the wound. Its use, however, must be attended with care, since in a few cases it will be found too active. It will then be well to alternate it with some washing preparation.

Balsam of Peru gauze will be found very efficacious, especially if alternated every few days with the above-mentioned wash. This gauze causes rather finer and apparently more resisting granulations than most other forms of dressings.

Stimulation may also be brought about by some of the milder caustics used at the time of dressing and followed by boric acid solution or some mild form of application to be left in place for twenty-four to forty-eight hours.

For this, a saturated solution of potassium permanganate may be painted over the ulcer, and this washed off with hydrogen peroxide, followed by sterile water and the dressings of boric acid then applied. This must not be used more frequently than every fourth or fifth day, and often causes some pain. Nevertheless, it is attended by most gratifying results in many cases.

*Silver Nitrate.*—The better employment of this remedy is by brushing over the wound surface with a solution of 40 grains of this substance in an ounce of water, or by touching the granulating surface with the stick. This may or may not be washed off, and is to be followed by a wet boric acid dressing.

One or two weeks of such treatment usually shows a marked decrease in the size of the ulcer and improvement in the character of the granulations. It may now be necessary, if the ulcer has again reached a stage of sluggishness, to repeat the incisions around the edge to again start the closing in of the ulcer.

In many cases it will be found necessary to treat the surrounding skin for inflammatory conditions. To best accomplish this, gauze pads saturated with some of the above solutions are placed over the ulcer and then the whole covered with lint upon which is spread such ointment as the cutaneous condition suggests. Lassar's paste is especially valuable.

Rest in bed with elevation of the part is often of advantage, but should only be used as a last resort if the patient is dependent upon his mobilization for his support.

Massage and douches of alternate hot and cold water are useful in all cases. Later, when the ulcer becomes healthy and the granulations reach close to the surface the parts may be strapped with strips of zinc oxide plaster, three-fourths of an inch wide, applied alternately from opposite sides, beginning below and extending well above the ulcer and not allowing the ends to meet within an inch or more. These may be left in place for a week or ten days and give very pleasing results.

Skin grafting is performed in some cases, but the results are inferior to those of the same procedure in case of burns and more acute conditions.

After a cure has been effected, a Raudolph elastic bandage should be worn indefinitely and the leg doused with cold water and rubbed with alcohol every night and morning.

Constitutional treatment consists in hygienic measures as regulative of the diet and bowels and the treatment of other chronic disorders. Tonics containing iron, arsenic and strychnine are valuable, as they stimulate the circulation, improve the quality of the blood, and the arsenic often removes the eczematous tendency which frequently precedes or accompanies the ulceration.

Syphilitic ulcers respond readily to any form of local treatment if they are recognized as such, and active constitutional treatment is carried out. Creolin solution (a half ounce to a pint of water) is, however, especially useful in these cases for overcoming the odor and removing the slough.

In conclusion, let us say that even after large and careful experience, a line of treatment cannot always be selected at first to suit the case in hand, and it is often necessary to change the agents employed, and at times have recourse to ointments and various soothing and astringent dusting powders.

## SOME PHASES OF CRANIAL SURGERY.*

BY GILBERT GEOFFREY COTTAM, M.D.,
OF ROCK RAPIDS, IOWA.

Without attempting to cover more than a mere fraction of the ground now occupied by cranial surgery I wish to invite your attention to a few points that may prove of interest at this time.

We realize to-day, more than ever, that the complex anatomy and the incomplete knowledge of the physiology of the brain, coupled with the element of uncertainty of diagnosis and operative result, all conspire to make the study of this

* Chairman's Address, Section on Surgery, delivered at the Fifty-second Annual Meeting of the Iowa State Medical Society, held in Sioux City.

branch a most perplexing matter and these features also explain why more headway has not been made and why the field is an unattractive one for the dilettante or the sensationalist.

To learn what to unlearn has, indeed, been one of the hardest problems for investigators to solve and the results have become evident by the fact of there remaining more shattered ideals in the form of rejected fundamental teachings and abandoned operations than in any other branch of operative surgery.

This, however, is true progress. The utter refusal of the present age to be bound down by fallacious tradition has produced remarkable changes within the generation and promises well for the future, but we must not blind ourselves to the fact that, in brain surgery especially, much that we are prone to regard as proven and permanent to-day may to-morrow be ruthlessly condemned. The logical deduction from this is that the work of to-day should rest on a surer foundation and that we should profit by the mistakes of yesterday.

If we carefully analyze the history of the recent past, to say nothing of more remote times, we cannot fail to be impressed with one especially notable fact, namely, that experimental procedures unsupported by a sound pathology have invariably been unproductive of results and, per contra, wherever pathological conditions have received a correct interpretation, there have followed the permanent advances, in cranial surgery. Let me cite examples. Of the pathology of epilepsy we know nothing, but when the era of clean surgery was inaugurated and cerebral localization began to be a little understood it was thought well to revive the ancient operation of trephination for this condition, removing the so-called epileptogenic center in the true Jacksonian, or the depressed area in the traumatic, cases. The immediate results were encouraging, but it has come to be known that almost any operation on the cranium will cause temporary improvement in an epileptic, only to be followed by relapse later, and such proved to be true in this connection. Then a flank attack was made by Alexander, of Liverpool, who, proceeding on the theory that an increased blood supply was responsible for the cortical irritation, sought to diminish it by ligation of the vertebral arteries. This also failed. Later, Chipault, assuming that cerebral anemia was the causative condition, advocated excision of the cervical sympathetic ganglia, for the purpose of augmenting the supply of blood to the brain and this, too, after attracting some attention, fell into disrepute. The three-year limit has been the Waterloo of all operations for epilepsy up to the present time and the results show that it is useless to proceed further until we know something of the real nature of the affection itself. This applies to microcephalus, hydrocephalus, idiocy and general paralysis of the insane, the pathology of which we either know nothing of or else have learned enough about to indicate that the operations devised for their relief were based upon faulty deductions and have therefore very properly been abandoned.

It may, then, very pertinently be asked whether our incomplete conception of the pathology of the central nervous system constitutes the only barrier to progress in its surgery and we must admit that there are other factors to be reckoned with. Of great importance is the matter of cerebral localization, upon which so much light has been shed in the last thirty years and of which so much remains yet to be revealed. It is true that the function of a large part of the cortex has been accurately mapped out in the physiological laboratories. It is also a fact that comparatively little of the knowledge so acquired is available for practical purposes and to harmonize the pathological conditions with the clinical manifestations is one of the unsolved problems of the present which we hope the future will explain. It is coming to be recognized that injuries severe enough to produce focal symptoms at all are generally accompanied by sufficient laceration of the surrounding and distant brain substance, with resultant hemorrhages of various degrees, to render a localizing diagnosis impossible. Krönlein says "In complicated cases without history the surgeon is glad to make a diagnosis in general, or to know on which side to trephine."*

In abscess or tumor cases the same difficulty may be met with owing to the very gradual enlargement of the lesion and consequent adaptation of the brain to the increased pressure. Irradiation fractures, causing hemorrhage on the opposite side from that upon which the injury was inflicted—the modern view of the old *contre-coup* theory—may also prevent a localizing diagnosis by the fact of total paralysis being thus produced. A typical instance of this came under my observation ten years ago. The following is a brief history of the case. A heavy, middle-aged teamster fell from his wagon, striking the posterior part of the right lateral surface of his head upon the hard ground, sustaining a depressed fracture of the posterior lower one-fourth of the right parietal bone, becoming totally paralyzed and comatose forthwith. A large flap was turned back and the fragment elevated. There was slight temporary relief, but the grave symptoms soon recurred and death ensued within forty-eight hours after the injury. At the post mortem it was found that the fracture had followed the lambdoidal suture around the back of the skull to the opposite side until it reached the asterion, when it divided into two branches, the upper of which terminated just anterior to the zygomatic tubercle, the lower again dividing into two branches which ended in the mastoid process. On opening the skull it was found that the left lateral sinus had been ruptured by this fracture, producing a large subcranial hematoma which extended as high as the superior temporal ridge, while under the dura of that side was another

* Quoted by S. C. Plummer in "The Hartley-Krause Flap in Hemorrhage from the Middle Meningeal Artery," Annals of Surgery, Vol. XXXVI, p. 597.

large accumulation of blood, covering the entire hemisphere of the brain.

Lesions in the frontal cortex are devoid of special localizing symptoms, but suppuration in this region may be accompanied by marked cachexia, of which the following case is corroborative: A. B., a boy aged seven years, was kicked in the right fronto-parietal region by a horse, receiving an open fracture close to the pterion and became immediately comatose. The wound was stitched and dressed antiseptically by the attending physician. Coma continued for two days. On the third day measles developed. Recovery ensued without further incident until four weeks after the accident, when the patient began to complain of frontal headache, vomiting at times. The temperature became irregular and occasionally attacks of spasmodic convergent strabismus were noted. There was marked emaciation, with anemia. Seeing him in consultation at 3 A.M. five weeks after the receipt of the injury I found the temperature 98° F., the pulse 110: patient restless but rational and complaining of frontal headache. He was much emaciated. There was no ocular irregularity and the fundus was not examined. The site of injury was tender on firm pressure: the original wound in the scalp was entirely healed. On turning down a large flap a fragment of bone measuring three-fourths by one-half inch was found driven into the brain substance and under it about two drams of pus, which spurted out with some force on removal of the fragment. The opening in the skull was enlarged with rongeur forceps, the flap replaced and efficient drainage provided for. The patient succumbed to pulmonary edema eight days afterward, and no autopsy was performed.

These cases are simply types illustrative of the fallacious import of localizing symptoms. Realizing this, it becomes necessary to consider the only other available method of diagnosis, exploratory operation, and I think that it will be freely conceded that the development of our present technic makes this a much less formidable undertaking than heretofore. By means of the osteo-tegumentary flap it is possible to make the necessary investigation of the suspected area and afterward secure a satisfactory adjustment of the anatomical relations involved. If necessary the entire motor area of one side can be explored through one flap without compromising the subsequent integrity of the coverings. The methodical exploration of the brain for fluid can be carried out either by Fenger's canulated sounds, or better by the use of a thin, slender spatula, which may be inserted in every direction and is equally serviceable to detect the presence of new growth or fluid.

It is well to observe, in this connection, that chemical antiseptics have no place in brain surgery, but the most rigid asepsis is even more essential than in abdominal operations, where we have a peritoneum to cover a multitude of sins. Prolonged exposure of the brain, too, is likely to prove disastrous by the production of profound shock and must always be avoided. The recent work of Horsley and Macewen in the removal of growths in two stages affords a valuable suggestion for the prevention of shock. If we read between the lines of many reports of cerebral operations we cannot but conclude that the patient's welfare would often be better subserved did the operator content himself with trying to do less. I believe that this applies with especial force to the management of open, or compound fractures.

The objects here to be accomplished are: (1) limitation of infection, (2) hemostasis and, (3) relief of pressure. If all of this can be done, as is frequently the case, through the original opening, what is to be gained by systematically performing trephination in each and every case, as so many text-books direct? This point was brought forcibly home to me in a case which had to be treated in very unfavorable surroundings, causing me to hesitate over the question of doing a radical operation and finally deciding in the negative, although the injuries were such as under ordinary circumstances are usually taken to warrant operative interference. The history of the case is as follows: Mrs. M. R., aged twenty-five years, was struck several times on the head with a dull-edged hatchet, rendering her unconscious at once. The head being shaved, I found four separate and distinct open, depressed fractures, one being situated on the sagittal suture midway between the glabella and inion, another about one inch to the right of the external occipital protuberance, the other two close together near the left squamoparietal suture. The fragments were driven through the dura into the brain in every instance except the first mentioned, which was in the superior longitudinal sinus. The removal of all the fragments was done by means of a narrow-bladed forceps and the edges of the openings in the skull carefully examined for depressed pieces, which were elevated in like manner. The wound in the superior longitudinal sinus bled furiously on removal of the fragment; this was controlled by gauze packing, which is the proper and only method of dealing with injuries of these vessels. The other openings were all drained without suturing. Hot sterile salt solution was employed throughout to wash away débris, etc. The patient made an uneventful recovery.

Under no circumstances should the scalp in an open fracture of the skull be stitched when such stitching interferes in the slightest degree with the freest possible drainage. The teaching of some writers that the proper practice is to convert them into closed or simple fractures at once is absolutely pernicious. Every accidental open wound must be regarded as infected and we have no right, in the present stage of our knowledge, to assume otherwise.

Before closing, permit me to plead for the utmost simplicity of technic in all operative procedures upon the cranium and its contents. There is a tendency nowadays to introduce a bewildering array of new and modifications of old appliances into surgical work, not one in twenty of them of any real practical utility. The trephine

is, of course, obsolete and merits no place in a modern surgeon's equipment; its place has been taken by the chisel, the rongeur and the DeVilbiss device. With these, in practical hands, any modern surgical procedure on the skull can be executed. They are inexpensive, can be carried anywhere and may be adapted to other purposes. They do not get out of order, like surgical engines, nor break, like Gigli wire saws. It is quite unnecessary to adopt Schäfer's method of controlling hemorrhage from the scalp by an encircling rubber band; such few vessels as bleed are better caught up at once by hemostats, which then hold down the flap by their own weight and obviate the necessity of an assistant with a retractor. Again, too, would I put in a word for the osteotegumentary flap, it being the simplest method of entering the skull for the relief of middle meningeal hemorrhage, growth or abscess of the brain, or for purely exploratory purposes.

## MEDICAL PROGRESS.

### MEDICINE.

**Aortic Insufficiency after Trauma.**—Severe injury may result in the rupture of an aortic valve where atheroma is present, but it is less commonly known that the same may occur in perfectly healthy valves. Aortic insufficiency follows, but extensive vegetation at the tear may also narrow the orifice. It is generally stated that an exceedingly loud and rough murmur speaks for a traumatic etiology in doubtful cases but this is not always so, according to T. Struppler (Münch. med. Woch., July 14, 1903) who gives the detailed history of a case with a very indefinite murmur. Sometimes, on auscultation, no murmur can be heard at all.

**A Case of Portal Thrombosis.**—As in most cases of portal thrombosis, the one published by O. Schulz and L. R. Müller (Deutsch. Arch. f. klin. Med., vol. 76, No. 6) was of unknown etiology. A constantly recurring ascites, which required frequent tapping was the prominent symptom. Since the patient did not lose any weight despite the large amounts of albuminous fluid which were removed, the fluid itself as well as the organ after death were studied exhaustively. It was found that the secretion of bile does not suffer in portal occlusion, nor are the liver cells changed pathologically, though the entire liver is smaller and its connective tissue proliferated so as to give the organ a lobulated appearance. Where anastomosis between the general and portal systems is insufficient, as in this case, marked ascites follows. But the transuded fluid is not entirely lost for the organism; it is an interesting fact that the parietal peritoneum and the peritoneal coat of the liver undergo extensive changes whereby an increased absorption of the nutritious fluid is possible, thus permitting the patient to remain in comparatively good condition for many months. These changes manifest themselves macroscopically in thickening and microscopically in proliferation of the capillaries, small veins and lymphoid cells in the subperitoneal connective tissue. These alterations are typical for portal obstruction and do not occur in ascites due to general venous stasis. The amount of nitrogen in the fluid was influenced to a certain extent by the character of the food; thus the amount of albumen in 25 liters could be made to vary from 177 to 335 grams. Certain extractives of unknown composition were also present whereas urea, albumoses and peptones occurred only in traces or not at all and the amount of sugar was never more than a few tenths of one per cent. Albuminous food diminished the amount of fluid transuded and vice versa and by restricting fluids, the next puncture could be postponed for a few days.

**Arterio-sclerosis as a Cause of Nervous Disease.**—The frequent presence of arterio-sclerosis as a cause of apoplexy is a matter of common knowledge but it is not as generally realized that many of the temporary and apparently neurasthenic symptoms which occur in men of middle age have also an organic basis in the sclerosed condition of the blood vessels. M. A. Starr (Med. Rec., July 4, 1903) believes that too little attention has been paid to this causal factor of nervous disturbances and a warning of more serious trouble is frequently disregarded until too late. Most commonly a disturbance in the mental action is first noticed which the patients describe as dulness or hebetude. Difficulty in clear thinking, an irritability of temper and lack of control of emotions are manifested. Others complain of temporary sensations of numbness, irregular darting pains, ringing in the ears or a sudden dimness of vision being not uncommon. Thus it is always advisable to examine closely the arterial system of a middle aged man complaining of these indefinite and apparently neurasthenic symptoms. Furthermore, the condition of the vascular walls has an important etiological relation to various spinal cord lesions among which may be mentioned anterior poliomyelitis, bulbar paralysis and ophthalmoplegia. Although most of these cases are infectious in origin, nevertheless vascular disease has been found to be the basis of the lesion by various investigators in the more unusual forms of the disease. Myelitis and combined sclerosis have also been recently found apparently secondary to vascular changes. Diseases of peripheral nerves are also occasionally due to endarteritis in the small vessels which accompany them and neuralgias may frequently be brought into the same category. It is not intended to urge vascular changes as the usual or important cause of these affections but that they should not be overlooked as an occasional factor. In the treatment of these various conditions drugs never seem to be of much permanent use. General hygienic and dietetic measures are as a rule more efficacious. A great variation in the pulse tension is frequently noted and the author believes that there is an internal secretion which regulates this tension. His observations upon many cases of Basedow's disease and myxedema have led him to the belief that the secretion of the thyroid gland exerts a very marked influence upon the pulse tension. The pulse is invariably soft in Basedow's disease in which there is supposed to be an excess of this internal secretion and he has repeatedly noted the constant therapeutic effect of the administration of thyroid extract in lowering tension. Thus in conditions of temporary high tension great benefits are obtained from its use and no matter what the underlying cause may be the effect seems equally reliable. In various cases of migraine and in those conditions of vertigo, headache and confusion of mind which attend a high-tension pulse, and which are associated very often with a lithemic state the addition of thyroid extract to other remedies will give marked relief. For continued use also, when the tension is more constant, the thyroid extract seems to be more beneficial than nitroglycerin.

**Increasing and Diminishing Body Weight.**—The frequency with which the physician is consulted with the hope of rectifying an extreme condition of body weight in either direction not due to pathological causes makes this subject a very important and interesting one. M. Einhorn (Med. Rec., July 18, 1903) enters into the consideration of the amount of food necessary

for the ordinary maintenance of the body weight and the supply of energy for the daily work. It was formerly supposed that the more food supplied to the animals organism the more material was burned up. It has frequently been proven, however, that the organism does not burn up food introduced in excess but rather utilizes it and converts it into fat. On the other hand, the body consumes just as much material even when no food is taken, using up its own substance, fat and muscles. It therefore follows that the amount and kind of food ingested is the prime factor in the solution of this problem. Leanness is met with, although rarely, in persons who are perfectly healthy. They are usually of a vivacious temperament doing a great deal of work and eating only moderately. To increase the body weight one should inquire minutely how the patient has lived, what kind of food and how much he has taken with every meal. A diet list should include as great a variety of food as is compatible with the condition of the case. If the amount of food ingested be sufficient the beverages taken with the meals should be more nutritious. Less coffee and tea and more milk and cream should be taken. Two or three light extra meals may be given with advantage. About one quarter pound of butter should be taken daily. Butter is an easily digested fat and on account of its high caloric value is especially suitable. When the appetite is poor it will generally be found that bread and vegetables as well as milk and eggs can be taken even if a dislike for meats exists. The addition of olives, lettuce and horseradish sometimes increases the desire for meats. A glass of water stimulates the appetite while eating and induces a larger consumption of food. Outdoor life and moderate exercise are of value for the appetite is thus improved and by satisfying it the increased loss of heat through muscular work will not only be compensated but probably an excess of food will be ingested without trouble. To reduce body weight two methods are possible, diminution of the amount of food taken and second, increase of amount of work performed. A rapid and safe method is that suggested by Weir Mitchell who advocates that the person be placed on a diet of skimmed milk alone, with the usual precautions, or at once give skimmed milk with the usual food and in a week put aside all other food save milk and all other fluids. When the amount of milk necessary to maintain the weight is determined it is gradually diminished until the patient is losing a half pound a day unless the decrease is not well borne. Considerable rest in bed is necessary when so rapid a loss is desirable, massage and Swedish movements are also beneficial. Oertel and Zuntz depend largely upon the increased amount of work done. By carefully regulating the amount of work done and the food ingested the regulation of body weight can be controlled to a great extent even when the daily work of the patient is continued and when recourse to these more rapid methods is impossible. In increasing the work the patient should never be allowed to become exhausted. The accelerated heart action and respiration due to the exertion should return to normal ten minutes after beginning to rest. Thus it will be seen that harmful and, at least, very annoying conditions of the body may usually be entirely cured if these simple means (diet and muscular work) be carefully studied and regulated.

**A Case of Syphilitic Polyarthritis.**—The patient dates the primary lesion from five years ago. The course of the disease did not seem to be typical, although the diagnosis is undoubted. A few months before admission to the hospital there appeared suddenly pain in the left great toe, and in the left sole; the next day the pain spread into the ankle of same side; in a week the knee-joint was attacked. The pains were especially aggravated at night. Later on the right knee was invaded. Treatment for "chronic articular rheumatism," though energetically applied for a long time, failed to produce any results. The epiphyseal ends of the bones at the attacked joints were markedly thickened and tender to pressure. Patient walks with difficulty and pain; is hardly able to flex his knees, and is entirely unable to extend them. Passive movements elicit crepitation. Left shoulder-joint appears to be thicker than the right, and abduction is limited to 45 degrees. The muscles of several joints are markedly atrophied. Villanen (Roussky Vratch, April 25, 1903) excluded rheumatic affection in view of the chronic course of the disease, the nocturnal exacerbation of the pains, the absence of any marked alterations in the skin over the affected joints, as well as of any febrile condition during the whole length of the attack, and finally the complete failure attendant on energetic antirheumatic treatment. Tuberculosis of the joints was excluded by the multiplicity of the affected joints, by the fact that no purulent exudations were detected in any of the joints, the low temperature and the absence of tubercular signs anywhere in the system. As a matter of fact the employment of iodide of potassium in conjunction with mercurial ointments improved the condition rapidly and radically. After a series of inunctions the patient began to feel better, gained 23 pounds in weight and walked with comparative ease. The author is inclined to consider this polyarthritis as belonging to the late period of syphilitic manifestations. The patient very likely entered the hospital at the period of transition from the secondary to the tertiary stage; and it was because of this that the mercurial treatment in conjunction with iodine was more effective than the iodine alone, as employed in the beginning.

**Sea Air for Pertussis.**—Though there is still some diversity of opinion as to the specific cause of whooping-cough the malady is pretty generally conceded to be of an infectious nature, say Dhourdin and Lalesque (Jour. de Méd. de Bordeaux, July 10, 1903). Hence the indications for its treatment are deemed by them to be dieto-hygienic, aseptic, microcidal and serotherapeutic. The asepsis of the condition is represented by all the hygienic conditions advised in virulent and contagious diseases generally: Aeration, isolation, disinfection of the apartment and sterilization of objects and clothing belonging to the patient. As to microbicides, but few are of any real service in pertussis and those which have done such excellent service in surgical practice are not available in medical diseases. Inhalations of ozone have proven of real benefit in the hospital treatment of pertussis by L. Delherm, who attributed the favorable influence seen from this method of treatment, to the antispasmodic properties of ozone. The author, however, believes it to be antiseptic as well, and a true germicide in bronchopulmonary affections. To the fact that ozone abounds in sea air the authors attribute the benefit derived in this affection from a sojourn at the sea side and they urge the advantages of such a change of climate in the treatment of pertussis.

**Acetozone in Amebic Dysentery.**—The interest which has lately been extended to this disease in the United States lends value to the report made by R. L. Kurtz (Medicine, August, 1903) of a sporadic case, which the author believes to have been due to infection from cats, an epidemic of the disease occurring among the felines in the town in which the patient lived. The history of the case extends over a period of about two years, the symptoms at the beginning leading to the diagnosis of gastric ulcer, until at a later date the *Amœbæ coli* was discovered in the stools. The emaciation increased and the patient finally died from a complication of causes. The autopsy showed extensive

pleuritic adhesions and numerous small abscesses and also a large cavity filled with pus. There were no evidences of tuberculosis. All the abdominal organs were adherent in a compact mass and several ulcers were found in the colon. There was nothing in the early history of the disease to direct attention to the dysenteric character, and this coincides with the observations of others that there may be severe ulceration of the cecum due to amebæ without dysentery, the stools being normal. In this case it was also probable that there was an infection of the stomach some months before the beginning of the dysenteric attacks. All known forms of treatment were without results and only acetozone given internally and by irrigations (1-1,000), seemed to have any influence. On the eighteenth day after this treatment was begun, the mucus, blood and fetor disappeared from the stools, the temperature was lower and the abdominal tenderness diminished. The patient was, however, in extremis and it is probable that if the acetozone had been employed earlier, the results might have been different and the author also suggests that if the drug were injected intravenously it might reach amebic foci in other organs.

## SURGERY.

**New Operation for Congenital Ectopic Vesicæ.**—The only operaton which really gives good functional results in congenital ectopia of the bladder is that of Maydl, which consists in implanting the floor of the bladder into the gut. Since however a certain percentage of cases are always lost by subsequent ascending infection of the genito-urinary tract, J. BORELIUS (Centralbl. f. Chir., July 18, 1903) suggests in addition, an anastomosis at the root of the sigmoid flexure, between its two limbs, so as to divert the main current of feces away from the site of operation. There was occasion to try this method only once, with good result. The steps of the operation would be as follows: (1) Dissection of the bladder from its surroundings with the formation of a large, elliptical piece of the bladder floor, containing the ureters. (2) Opening of the abdominal cavity sufficiently to permit access to the sigmoid flexure. (3) Lateral anastomosis between its two limbs. (4) Longitudinal incision into the flexure with implantation of the excised bladder wall. (5) Abdominal sutures.

**Biliary Colic Without Calculi.**—It is often found during an operation on the gall-bladder, that the pathological findings are in many cases not nearly as severe as the clinical symptoms would have indicated. The report of two very interesting cases by H. KRUKENBERG (Berliner klin. Wochenschr., July 20, 1903) also shows that attacks of typical biliary colic may be caused by a displaced gall-bladder, without the presence of any other lesions. Operation was done in two female patients who suffered greatly from such attacks and in which no signs of stones or disease of the gall-bladder were found. The fundus of the latter was found markedly displaced and its body stretched out, but there were no adhesions, and the walls were not changed in any way. In each case the gall-bladder was sewed to the abdominal wall and drained after an interval. A complete cure with cessation of all symptoms resulted. The author designates the condition as a migrating gall-bladder and advises operation in every case,—the gall-bladder also being incised to eliminate the possibility of any calculi being present.

**New Method of Appendectomy.**—Various methods have been devised by which the stump of an appendix may be treated so that there will be little danger of subsequent sloughing or infection of the neighboring peritoneum. E. RIES (N. Y. Med. Journ., July 4, 1903) objects to the method of dilating the stump and inverting it because the instrument must be passed into the cecum and withdrawn after the inversion along the serosa of the stump thus exposing the serosa to the possibility of infection. He recommends the separation of the mesentery and the amputation of the appendix about one-third of an inch from the base. The stump is then held by forceps and the escape of the contents prevented by simple traction in the cecum. A fine round straight needle with a thread at the very end of which is a thick knot, is introduced into the stump one-sixteenth of an inch from the cut surface from inside outwards. The needle is then passed back into the lumen of the appendix and on into the cecum and passed out through the cecum about one inch from the base of the appendix. Pulling on this thread inverts the appendix immediately in a most satisfactory way and its serous surfaces are in perfect apposition and are held there by mere traction upon the thread while a second needle, with a cat-gut thread, sutures, in three or four continuous stitches, the serosa of the funnel of the inverted appendix. The first thread is then cut close to the bowel and by gently rolling between the fingers is drawn back into the lumen of the bowel. The mesentery is then sutured over the base of the appendix. The danger from the perforation of the bowel wall has been found to be very slight as the experience with the Connell suture proves. Should a stricture or obliteration of the lumen prevent such an inversion this obstacle may be overcome by simply stretching or perforation and still there would be no fear of infecting the serosa of the appendicular stump.

**Treatment of Fractures.**—The article of D. JORDAN (Münch. med. Woch., July 7, 1903) gives evidence that the author is an enthusiastic believer in the massage treatment of fractures, combined however with immobilization, even where dislocation is absent. The massage consisted in stroking the limb in its long axis from the periphery to the center with increasing pressure, without however manipulating the actual site of fracture. Thus, a Colles' fracture was massaged, then a wet dressing applied and the arm fixed in a simple paste-board or wire splint till the next day when the massage was repeated. This treatment was continued until complete union had set in. Fractures of the forearm and of the condyles and epecondyles of the humerus were manipulated in the same way with the arm flexed to a right angle and in supination during the intervals. In fractures of the olecranon it is well to fix the arm in extension after every sitting, for three weeks; after this the arm is immobilized more and more in flexion. The absence of pain during massage shows that it is properly performed. Of seventy-three cases of fracture of the upper extremity, sixty-seven regained complete use of their limbs; the others, owing to advanced age or systemic disease had slight limitations of movement. Even where there is a constant tendency to dislocation, massage is useful, since it stimulates callus formation. In fractures of the lower extremity, massage is of marked advantage only when the break involves a joint; it should here be used with ambulatory dressings.

## THERAPEUTICS.

**Treatment of Atrophic Rhinitis.**—The employment of acetozone, the new organic peroxide formed from the anhydrids of benzoic and acetic acids, is highly recommended in the treatment of this condition by J. M. BROWN (Medicine, July, 1903), who used it successfully in three severe cases. After removing the crusts, the acetozone is applied and a nasal spray used daily, consisting of a solution of one-half of one per cent. of pure acetozone in a neutral organic oil.

**General Anesthesia with Chloride of Ethyl.**—The advantages of chloride of ethyl—kelene—are set forth

by J. Vanverts (Nord Méd., July 1, 1903). In his experience it allows of easy and rapid anesthesia and is free from the discomforts and dangers of chloroform and ether. The graduated tubes containing from one to two ounces (25 to 50 c.c.) permit an exact knowledge of the amount used, which should not, as a rule, exceed one ounce (25 c.c). The fluid may be used upon a mask or compress, 1¼ drams 5 c.c.) being given; ½ to ¾ drams (2 to 3 c.c.) for children and 1½ to 2½ drams (6 to 10 c.c. for alcoholics) and this dose repeated at five-minute intervals during the operation, to the limit of 25 c.c. It will thus be seen that chlorethylization is best adapted to short operations, though it may be advantageously employed in longer operations as a preliminary to chloroform or ether. By this means the discomforts and dangers of chloroform and ether anesthesia are overcome and a smaller quantity of the latter drugs may be used. Analgesia is produced by one to two inhalations, provided these are sufficiently deep and air has not been inspired; and complete anesthesia generally ensues in three minutes. This is indicated by muscular relaxation and sometimes by dilation of the pupil and abolition of the corneal reflex. Anesthesia continues for three minutes after inhalation of 1¼ drams (5 c.c.) of kelene, when the dose must be repeated if it is desired to prolong anesthesia; but complete analgesia persists for from fifteen to twenty minutes after withdrawal of the drug, the patient regaining consciousness but suffering no pain during the completion of the operation, should it be deemed expedient to continue the work in this condition. Not the least of the advantages claimed for chlorethylization is the absence of initial excitement, in ordinary cases; though a slight excitement—not in the least comparable to that produced by other anesthetics—is seen in hysterical and alcoholic subjects and when air gains access to the patient. Both pulse and respiration are normal in kelene anesthesia. As a rule, nausea is absent when the patient awakens, and no ill effects are felt. An objection to kelene as a general anesthetic is the occasional failure to obtain the complete muscular relaxation essential to the performance of certain operations, such as reduction of dislocations; in which event the operator must hold himself in readiness to continue the work with another anesthetic. The rapidity with which the patient arouses, necessitates repeated doses during the operation; and as the amount given should not exceed 1 ounce (25 c.c.) kelene is ill adapted to long operations. As a preliminary to ether or chloroform it is, however, desirable in more lengthy surgical work.

**Yohimbin as Anesthetic.**—From the article of C. Magnani (Münch. med. Woch., July 14, 1903) it seems that yohimbin possesses unexpected anesthetic properties and that it is destined to play an important rôle in minor surgery. Five drops of a 1-per-cent. solution injected into the arm so as to form a wheal, rendered an incision down to the fascia alsolutely painless. The anesthesia lasted fully 1¾ hours without the appearance of toxic symptoms or alterations in the muscular tonus. Reviewing all the drugs which have been recommended to anesthetize the eyes, it seems that disadvantatges adhere to each of them, so that yohimbin may ultimately fill a long-felt want.

**Antistreptococcus Serum in Erysipelas and Puerperal Sepsis.**—The results of the employment of antistreptococcus serum published so far are so contradictory that no definite idea can be found as to its utility as a therapeutic agent. Ravitch (Prakt. Vrach., No. 25, 1903) presents 2 cases of erysipelas and 2 cases of puerperal sepsis in which he used the serum. The first was a typical case of facial erysipelas in a woman 50 years of age. The disease was in its fifth day of development, spreading rapidly and unyielding to various remedial agencies such as carbolic acid, ichthyol, etc., when 5 drams (20 c.c.) of antistreptococcus serum were injected; improvement followed on the next day, and in the course of a week the patient was rapidly convalescing. In the second case the favorable results of the injection manifested themselves on the third day. Of the puerperal cases the first became septic soon after delivery; when seen by the physician during the third week after confinement she presented typical signs of sepsis, pain in the uterus, daily sweating, offensive lochial discharge; abdomen somewhat distended and pronouncedly painful; 5 drams (20 c.c.) of the antistreptococcic serum was injected, followed on the next day by a double dose; improvement was gradual but undoubted, and in the course of a month the patient was discharged well. In the second case, that of an adherent placenta that necessitated extraction, sepsis was quite pronounced during two weeks, at the end of which an injection of the serum was made; but as improvement was not observed, and the supply of the serum was exhausted, routine treatment was resorted to, until a new supply of the serum was injected on the fifth day. Unfortunately the result of the treatment became obscured through an unexpected complication of pneumonia from grip. However, the patient eventually recovered with a somewhat diminished mobility of the uterus. Notwithstanding the small number of cases in which the serum was employed the results obtained are undoubtedly interesting and may lead to further trials.

**Silver Nitrate Injections in Tuberculosis.**—Good results are reported by H. T. Bass (International Med. Mag., July, 1903) from repeated injections of silver nitrate into the neck over the vagus nerve. Five drops of a 2½-per-cent. solution were generally employed. There seems to be nothing else which is so efficacious in modifying favorably such a large number of symptoms and even in advanced cases the cough and expectoration are always improved. In the incipient forms it has a most powerful influence for the good, bringing about the quite unexpected changes.

**Veronal.**—As excuse for discussing a new hypnotic, T. R. Offer (Centralbl. f. d. ges. Therap., July, 1903) states that in chronic cases of insomnia one is often obliged to run through the entire list to avoid tolerance. Patients will also get accustomed to veronal in time, yet one can bring about a natural sleep with small doses for quite a period. It is best to begin with 7½ grains (half a gram) and to increase the dose daily by ¾ grain (five centigrammes) up to 15 grains (one gram) or until depression the following day shows that all of the drug is not excreted.

**The Pharmacological Action of Optical Isomers.**—That protoplasm has the power of distinguishing between the various isomeric forms of sugar and tartaric acids, is well known, according to A. R. Cushny (Proc. of the Amer. Physiol. Soc., Amer. Jour. of Physiol., July 1, 1903). Fisher has shown that this power is also shared by the ferments. The mammalian tissues also oxidize one of the isomers more rapidly than the other. The author's experiments were performed with levohyoscyamine and the racemic form, atropine. It was found that these acted equally strongly on the terminations of the motor nerves in striated muscle in the frog, on the frog's heart muscle and on the central nervous system in mammals, while atropine had a more stimulant action on the central nervous system of the frog. Hyoscyamine acted almost exactly twice as strongly

as atropine on the nerve terminations in the salivary gland, heart, and pupil in mammals, from which it was inferred that the racemic atropine liberates the two optically active forms when dissolved, and that the dextro-hyoscyamine is practically devoid of action in these organs. This was confirmed by examintion of some dextro-hyoscyamine. It was found that levo-hyoscyamine acts 12 to 16 times as strongly on the salivary secretion as dextro-hyoscyamine, and about 12 to 14 times as strongly on the terminations of the inhibitory cardiac fibers. The terminations of the nerves in the salivary glands, heart and pupil can therefore differentiate between these optical isomers.

**A New Digitalis Preparation.**—An attempt to obtain a uniformly active, sterile and non-irritating preparation of digitalis for subcutaneous and internal administration, has resulted in the production of "digitalone," which is claimed by its discoverer to obviate the difficulties attending the administration of the ordinary preparations of digitalis. In a recent article, E. M. HOUGHTON (Medicine, August, 1903) states the manner in which the drug is prepared and also gives the result of animal and clinical tests. He employed a large number of menstrua for percolating digitalis leaves, the irritating properties of each percolate being determined by injecting small quantities subcutatneously into guinea pigs and chloroforming them some hours later and examining the site of inoculation. Blood pressure tracings from the carotid artery of the dog were also made to determine whether the drug was capable of producing a typical digitalis action. Finally a non-alcoholic fluid preparation was obtained (the menstruum is not, however, stated) which produced characteristic slowing and increased systole of the heart, accompanied by marked increase in blood pressure. As it contained no alcohol or other preservative, chloretone was added (about six-tenths of one per cent.), to prevent bacterial decomposition. The fluid has been adjusted to the strength of a 10-per-cent. tincture by determining the minimum lethal dose per gram body-weight for frogs and comparing the results with those obtained from the injection of known quantities of a standard preparation of digitalis under the same conditions. Animal and clinical experiments have shown that the drug is uniform, non-irritating when given subcutaneously, readily absorbed and produces the typical digitalis action when given per rectum, internally, hypodermically, or intraveneously, is aseptic and remains so if stoppered. The dose is from 5 to 15 minims subcutaneously, 10 to 30 internally.

## PHYSIOLOGY.

**Contributions to the Physiology of Vision.**—Together with other original discoveries connected with the physiology of sight, C. BAUMAN (Pflüger's Archiv, Vol. 95, Nos. 7-8) finds that various colored lights influence the power of accommodation to a varying degree. From a piece of red glass 15 mm. square a vertical strip 1 mm. broad was cut out in the middle; from another piece of glass of the same size and shape but colored blue, a horizontal medium strip of the same size as in the former case was removed. The two sets of colored glass were placed in the stereoscope. Upon looking through the latter the colored glasses naturally appeared superimposed, but the clefts, vertical in one case and horizontal in the other, did not appear of the same breadth. The vertical cleft in the red glass seemed broader than the horizontal cleft in the blue glass. The reason assigned for this phenomenon is that red light arouses the eye to a more powerful accommodation than blue or yellow light. This stronger accommodation is not different from that which the eye exerts in looking at a near object. This stronger accommodation of the eye aroused by red would lead to the conception that in this way the attention of man and animals is stimulated to a considerable degree. If one is unexpectedly brought face to face with a broad red surface one feels distinctly the effort of the eyes trying to accommodate themselves to red, and at the same time is experienced a sensation of fluctuation of the image. This latter results from the apparent spatial change that one thinks takes place in the position of the red surface. The image of this surface is the same as that which would be aroused by that of any other color at a nearer distance, and one therefore has the impression as if the red surface is rapidly approaching; this approach is intensified by the apparent recession of the non-red portion of the picture. That animals are markedly disturbed by red objects has been known for a long time, and this irritation can be easily explained on the basis of the stronger accommodation for red. The bull in whose presence a red cloth is brandished experiences the same impression as man; he sees in the red cloth a rapidly approaching object which he interprets as an enemy, and he rushes forward to meet it. To attribute this stimulus to the fact that the beast imagines he sees blood, is to credit him with an intelligence he does not possess.

**Is there Vasomotor Right-handedness or Left-handedness?**—This question is answered in the affirmative by E. CAVANI (Archives Italiennes de Biologie, June 10, 1903). In an examination of a large number of right-handed and left-handed individuals, he finds a vasomotor reaction more intense and more rapid on one side of the body than on the other. Generally the conditions more favorable to the vasomotor reaction are found on the side of the body more able to put forth the greater muscular effort. The difference in time between the reactions on both sides of the body may amount to one second. Very probably, the vasomotor asymmetry is to be ascribed to the greater permeability or conductivity of the nervous routes in the extremities which have been more freely exercised, without excluding the possibility of the influence of the varying degrees of sensorial excitability in the two halves of the body or the corresponding halves of the brain.

**The Fatigue of the Vasomotor Apparatus.**—The centripetal portion of the vasoconstrictor mechanism and more markedly the centrifugal portion, present a remarkable resistance to fatigue, according to R. SCHINCKEL (Annales de la Soc. de Méd. de Gaud, 1903, No. 3). The author was not able to produce fatigue in the centripetal vasoconstrictor filaments of the sciatic nerve until after at least one hour of tetanization. As to the vasoconstrictor nerves of the spinal cord and of the splanchnic nerve, a prolonged uninterrupted tetanization lasting two hours was not able to produce complete fatigue in the peripheral vasoconstrictor apparatus. During the excitation of the centripetal nerves, the vascular tone is slightly diminished. Fatigue of the vasoconstrictor apparatus is characterized by the appearance of marked undulations of the vascular tonus.

**Physiological Cholemia of the Mother and Newborn.**—The comparative study of the blood of the mother, new-born and umbilical cord, by A. GILBERT, P. LEREBOULLET, and MLLE. STEIN (Annales de Gynéc. et d'Obstet., July, 1903), shows that the blood of the cord contains three times as much biliary pigments as the maternal blood, and the blood of the new-born contains one third as much more biliary pigments than that of the cord. There is therefore a physiological cholemia of the new-born, of marked intensity, although remarkably well borne, and it is this which gives rise to the secondary cholemia of the mother.

## A TOOTH FOR A TOOTH.

John Bull has most certainly established a reputation for conservatism and business acumen, if there is any faith in tradition, or virtue in heredity. But the latest action of the British war office in supplying false teeth gratis to soldiers, who have lost their own "as a result of active service," can hardly be classed as an exponent of their maxim of looking out for the pennies and letting the shillings take care of themselves. To be sure the amount involved, per head, is not large and the local dentists employed by the paternal government, can hardly regard Tommy Atkins in the light of a very remunerative gift horse, for the contract calls for the extraction of any and all teeth remaining, and the giving of an anesthetic, for which £1 is allowed. The "full sets" with the subsequent treatment of the gums and mouth are to be furnished at prices ranging from £2 10s. to £4 10s., so that the official dentists are much more apt to walk, than to ride in chaises, even if the appointments themselves do not go a-begging.

The weak notes in the harmony of this system seem to lie in the want of any middle register whatever, and are due to the fact that there appear to be no shillings of prevention to render unnecessary many pounds of subsequent cure. The English recruits have to possess a sufficient number of good teeth on joining the army, and the obvious thing to do would be to make sure that they were not allowed to decay. This could be easily accomplished by the appointment of contract dentists at the various military centers, who should examine the teeth of the enlisted men at least twice a year, and see that they were kept in good repair. This, however, is not the war office plan, which seems to be that the rank and file shall wait until they are incapacitated for the want of sound teeth, and then be sent to the dentist for a new set. An exchange of the old lamp of natural teeth, for the new one of artificial brilliancy.

That this might improve the facial aspect of the "Household Guards" is unquestionably true, but if the beneficent government would go a step farther, and give an eye for an eye—as well as a tooth for a tooth—the "Guards" would doubtless present a strenuous appearance, that would carry consternation to an opposing enemy and render the dark recesses of Spion Kop as gleaming and electric as San Juan Hill itself.

What they would gain in appearance, however, they would undoubtedly lose in efficiency, as it is unnecessary to say that the strength and health of men in campaigns depends more on their food, their ability to eat it in comfort and to masticate it thoroughly than on any other factor, and a regiment of men with sound digestions and a good commissariat, is better for practical purposes, than an army with banners. The roast beef of Old England is proverbial for its succulent tenderness, and her plum pudding has hardly to be bitten off or chewed. But neither of these national delicacies is served at the table d' hote of action, and the stalled ox, on the field of battle, is as rare as the contentment, which is popularly supposed to accompany the dinner of herbs.

According to the official army report nearly all the teeth that were lost or ruined in the South African war were damaged by the biscuits. The soldiers averred that they were almost as hard as granite, and that it was impossible to eat them, unless they were soaked overnight, or died, like the classic victim of the Mikado, a humorous death by being boiled in oil. Instances, says this report, are numerous of "men whose teeth were broken to pieces, and who came home with a mouth full of jagged edges."

No one could expect troops that had been exposed to danger and privation, and who had been fed on such fare, to have any stomach left for

either fighting or digestion. It is true that in the earlier days the invading forces subsisted on the surrounding country, and the army in Flanders certainly did not suffer even if it did not grow strong on the fruits of its pillage. But all this was before the magazine rifle had been invented, and in the period that antedates the reduction of "snipping" to one of the fine arts. At the present time the unlucky and starving British straggler would find his prescription for the cure of hunger filled by some substituting Boer, if not with food, at least with what would be more permanent and "just as good."

It cannot, of course, be claimed that the result of any war could have been changed by a previous course of operative dentistry, but it would certainly seem wiser, to the professional mind at least, for England to appropriate money for the preservation of the natural teeth of her soldiers rather than to expend it in the gratuitous distribution of artificial ones. Teeth are not Indians, and the best ones are they that are still alive.

In the event of a night attack, moreover, it would complicate matters extremely to have an entire command turn their trembling hands to the convenient tumblers of water before they even grasped their arms, and should the "two pun' ten" sets be trampled in the ground, it could hardly be expected that they—like the teeth of the dragon of Cadmus—should rise again in serried columns to repel the invading foe.

So, by all means, let the Army dentist attend to his duties in the earlier stages of his military patient's career. Let him back and fill, scrape and bridge, remembering only that uneasy lies the tooth that wears a crown, and that nature is superior to art, in all things, particularly when it is in the mouth of the British Grenadier.

### GALL-STONES IN THE YOUNG AND ACTIVE.

Since we are still much encumbered with the surgery of our grandmothers all experiments which tend to rid us of the fantastic reasoning and conclusions of their day are most heartily welcome. A roaring moral and intellectual bonfire once in a while not only consumes some of this old timber but lights the way for the finding of new fuel. Nevertheless, while we may be loud in our disapproval of the methods of the Chinaman we are at heart good followers of old Confucius. Who, for example, is there among us whose invective would not speedily be hurled against an iconoclast who should boldly assert that gall-stones were rendered impossible simply by practising the art of the Epicureans or the Romans *after* the fortieth milepost were past!

Copper-fastened, bent in, and clinched in the mind of most practitioners is the time-honored notion that biliary concretions rarely occur in the young and are almost of necessity the misbegotten scions of Bacchus and his genial kindred sprites.

Indeed it is no exaggeration to say that, in the light of our present widespread and generally accepted beliefs, under almost no circumstances would one be justified in advancing exploratory incision, even in supposed cholelithiasis in a youngster of say twenty years!

The decidedly revolutionary conclusion that young, active women from the laboring classes are the most frequent victims of gall-stones is advanced by Dr. Otto Hartmann. His experiments and reasonings are published in a leading article in the *Deutsche Zeitschrift für Chirurgie,* April, 1903.

As early as 1891, Naunyn, at the Tenth Congress for Internal Medicine, held at Wiesbaden, expressed himself as certain that gall-stones were of bacterial origin. It is now universally acknowledged that micro-organisms play a very important etiological part—any negation of this theory having been rendered untenable by the findings of Miyake and Mignot. These antipodeans, working independently of each other, produced artificial gall-stones in the bile tracts of guinea pigs and rabbits, one-half to one year after the introduction of colon bacilli into these passages. Hartmann, working from the opposite standpoint, has been able to demonstrate the presence of germs in over seventy-five per cent. of his recent series of forty-six cases. The work of Herter and others along these lines now shows very conclusively that the concretions in many instances are of bacterial origin.

Having decided this, it becomes of paramount interest to know how the germ obtains ingress. There are three more or less generally discussed paths of transit. The first and most freely admitted is the direct course through the lumen of the papilla of Vater from the germ-laden wall of the duodenum to the absolutely sterile regions of the upper biliary passages. Albeit, this is a short path and one remarkably straight, it is well known that there are numerous valves in the mucous membrane of the ducts which, combined with the normal bactericidal power of the bile, have been considered *the* factors in preventing infection.

A second, and much less probable mode of infection of the passages is through the medium of bands of adhesions through the dilated vessels of which the germs are supposed to flow.

The third, or so-called hepatogenous path of infection is from above downward. It presupposes a general infection of germs and their free distribution in the liver via the blood. That this condition obtains in typhoid is well known and it is after this disease that the concretions are very prone to form. Although the liver is very freely supplied with blood it cannot be looked upon as an organ gravely interested as are the kidneys in freeing the body of the germs—it is no germ-filter. Nevertheless, the very anatomical arrangement of the blood supply favors hepatogenous infection.

It is fair to suppose that any one or all of these three factors may be in operation in a given case. What, then, are the barriers, other than those already cited, which Nature throws up?
